(Received 14 September 2008; revised manuscript received 1 January 2009; published 24 March 2009)

We compare the Hanbury Brown–Twiss (HBT) and the thermal light ghost imaging schemes in both near and far fields. Both effects arise as a result of the intensity fluctuations of the thermal light and we find that the essential physics behind the two effects is the same. The difference however is that, in the ghost imaging, large number of bits information of an object needs to be treated together, whereas, in the HBT, there is only one bit information required to be obtained. In the HBT experiment far field is used for the purpose of easy detection, while in the ghost image experiment near (or not far) field is used for good quality image.

DOI: 10.1103/PhysRevA.79.033835 PACS number(s): 42.50.Ar, 42.50.Dv, 42.50.St

Recently, there is a heated discussion on the physics of the ghost imaging (GI) with thermal light [1–5]. For example, in a recent paper Scarcelli et al. [5] pose the question: “Can two-photon correlation of chaotic light be considered as correlation of intensity fluctuations?” The authors point out that near field is required for ghost imaging whereas the far field is required in the Hanbury Brown–Twiss (HBT) experiment. They also conclude that the chaotic (thermal) light ghost imaging could not be explained with classical mechanics, and the physics of the ghost imaging is not the intensity fluctuations of the thermal light (\(\Delta I_1, \Delta I_2 = \langle I_1 I_2 \rangle - \langle I_1 \rangle \langle I_2 \rangle\)) as in the HBT experiment [2,5], because large size of the source (near field) results in \(\langle \Delta I_1, \Delta I_2 \rangle = 0\) [2]. Instead, they claim that the essential physics is the two-photon quantum interference [2,5]. On the other hand, others disagreed with the conclusions in [5] by Shih et al. [3,4], and have concluded that the ghost imaging with classical thermal field is essentially a classical effect [3,4]. The controversy has persisted by another paper of Shih’s group [2] in reply to comments in [4]. The main objective of this paper is to resolve this controversy. In particular, we carry out a simple analysis that helps to clarify the difference and similarity between the GI and HBT, and hence shed light on the physics behind the two related effects.

Originally, the ghost image was achieved with entangled light [6]. In 2004 the formation of ghost image with thermal light was predicted [7] and the equation for the image formation is given in Ref. [8]. In 2005 the experiments on ghost imaging with thermal light were realized [9–11]. Since then, theoretical models are put forward to explain the thermal light ghost imaging [3,12,13]. Until today, far field is used in the HBT experiments, while near field (not-far field) is used in the ghost imaging experiments [2,5]. There is a first-order coherence for the far field, while the first-order coherence for the near field (not-far field) is small. A question of interest is whether the far field and the near field result in significantly different physics. We ask ourselves, what will be the results if we use the far field and the near field for both HBT and GI experiments. In the present paper, we address this question and discuss how the answer to this question reveals the physics behind the GI and the HBT effect.

The setup for the thermal light ghost imaging experiment is presented in Fig. 1 with a lens immediately behind the object focusing onto \(D_2\) (as a bucket detector [5]). The simplest HBT experiment [5,14] is the same except the detector \(D_2\) is placed at the location of the object with no object and lens. In both experiments, the source is a surface thermal light, for example a black box at a certain temperature. The thermal light from the source is split by a beam splitter and shines the two detectors, \(D_1\) and \(D_2\) through two paths, as shown in Fig. 1. The second-order correlation is detected by \(D_1\) and \(D_2\) in both the experiments. For the thermal light, the field statistics is Gaussian and this allows the calculation of the second-order correlation from the first-order correlation, i.e.,

\[
G^2(u_1,u_2) = \langle I_1 I_2 \rangle = \langle I_1(u_1) I_2(u_2) \rangle + \Gamma(u_1,u_2)^2 ,
\]

where \(\langle I_1(u_1) \rangle\) are the intensities at the points \(u_1\) and \(u_2\) on the planes of \(D_1\) and \(D_2\), and \(\Gamma(u_1,u_2) = \langle E^\dagger(u_1) E(u_2) \rangle\) is the cross correlation. The correlations at the detectors can be found out from the correlation at the source by correlation propagation method [14],

\[
I(u_1,u_2) = \langle E^\dagger(u_1) E(u_2) \rangle = \int \int \langle E^\dagger(x_1) E(x_2) \rangle h_{1,2}^\dagger(x_1,u_1) h_{1,2}(x_2,u_2) dx_1 dx_2 ,
\]

where \(\langle E^\dagger(x_1) E(x_2) \rangle\) is the two-point correlation function of the source. 

FIG. 1. (Color online) Ghost image setup.

PHYSICAL REVIEW A 79, 033835 (2009)
\[
\Gamma(u_1, u_2) = \langle E^*(u_1)E(u_2) \rangle \\
= \int \int \langle E^*_i(x_1)E(x_2) \rangle h_1^i(x_1, u_1)h_2(x_2, u_2)dx_1dx_2,
\]
where \(x_1, x_2\) are the points at the source plane and the integrals are within the source. Here \(h_1^i(x, u_1)\) are the propagation functions of the correlation from the source to the detectors along paths 1 and 2, respectively, which depend on the optical elements in the paths. For path 1, \(h_1^i(x, u_1)\) is the same in the two experiments.

\[
h_1^{H,G}(x, u_1) = \left( -\frac{i}{\lambda z_1} \right)^{1/2} \exp \left[ -\frac{i\pi}{\lambda z_1} (x^2 - 2ux_1 + u_1^2) \right].
\]

For path 2, we have different \(h_2(x, u_2)\) for the two experiments,

\[
h_2^H(x, u_2) = \left( -\frac{i}{\lambda z_2} \right)^{1/2} \exp \left[ -\frac{i\pi}{\lambda z_2} (x^2 - 2ux_2 + u_2^2) \right],
\]

\[
h_2^G(x, u_2) = \left( -\frac{i}{\lambda f} \right)^{1/2} \left( -\frac{i}{\lambda z_2} \right)^{1/2} \int duH(v) \times \exp \left[ -\frac{i\pi}{\lambda z_2} (x^2 - 2uv + v^2) - \frac{i\pi}{\lambda f} (2vu_2 + u_2^2) \right].
\]

where the superscripts \(H\) and \(G\) indicate HBT and GI, respectively. It is implicit that \(h_1^{H,G}(x, u_1)\) depend also on \(z_1\) or \(z_2\). In Eq. (5b), \(H(v)\) is the transmittance of the object and the integration is due to the bucket detector. In general, we should consider the two-dimensional imaging. However as \(x\) and \(y\) directions are independent, we only consider the \(x\) direction (one dimension). This however does not affect the physics.

For the thermal light at the source, the first-order correlation can be written as a series of the form [15,16],

\[
\langle E^*_i(x_1)E(x_2) \rangle \approx 1 - \alpha(x_1 - x_2)^2 + \beta(x_1 - x_2)^4 + \cdots
\]

with \(\beta/\alpha = 2.2\). This however does not allow for an analytical solution for the correlation functions of the field. We therefore approximate the first-order correlation function of the source to be a Gaussian Schell model source [15,17],

\[
\langle E^*_i(x_1)E(x_2) \rangle = G_0 \exp \left[ -\frac{x_1^2 + x_2^2}{4\sigma_i^2} - \frac{(x_1 - x_2)^2}{2\sigma_i^2} \right].
\]

Here we have a Gaussian distribution for the intensity of the source with the width \(\sigma_i\) and \(\sigma_p\) is the first-order transverse coherence width (correlation length) of the thermal light source. The normalized second-order correlation functions (HBT or GI) for the two experiments are

\[
\text{HBT or GI}(u_1, u_2, z_1, z_2) = \frac{\left| \langle \Gamma(u_1, u_2) \rangle \right|^2}{\langle \langle \langle \Gamma(u_1, u_2) \rangle \rangle \rangle}. \tag{8}
\]

First we consider the HBT experiment. The point detectors are located at \(u_1 \neq 0\) and \(u_2 = 0\) (transverse HBT). From

\[
\text{HBT}(u_1, 0) = \exp \left[ -\frac{\bar{u}_1^2}{\sigma_i^2 + \frac{z_1^2}{4\pi^2\sigma_t^2}} \times \exp\left( -\frac{\alpha}{\lambda z_1} (x^2 - 2ux_1 + u_1^2) \right) \right]. \tag{9a}
\]

which is a Gaussian distribution. For small \(\tilde{\sigma}_f/\tilde{z}\) (the far field), the decrease in HBT with the increase in \(\bar{u}_1\) is slow; see Fig. 2. That is to say, the smaller \(\tilde{\sigma}_f/\tilde{z}\) is, the easier the HBT can be measured experimentally. This is why the HBT experiment is usually done in the far field. However, the HBT experiment can be carried out in principle with the near field (or not-far field), because at \(\bar{u}_1 = 0\) we always have HBT=1, no matter what is the values of \(\tilde{\sigma}_f, \tilde{z}\), and \(\tilde{\sigma}_{t_g}\). Large \(\tilde{\sigma}_f/\tilde{z}\) (near field or not-far field) does not change the physical nature of the HBT experiment (the intensity fluctuations), but it increases the difficulty to realize the HBT experiment.

For the GI experiment, it follows on substituting Eqs. (4) and (5b) into Eq. (3) and with \(z_1 = z_2 = z\) the image is formed, we obtain the cross correlation function and the intensity,
\[ \Gamma(u_1,0) = \frac{4 \pi G_0 \exp\left(\frac{i \pi z_1^2}{\xi_1}\right)}{f^{1/2} \xi^{1/2}} \int d\bar{u} H(\bar{u}) \exp\left(-\frac{i \pi \bar{u}^2}{\xi}\right) \times \exp\left\{ -\frac{4 \pi^2 (\sigma^2 + 2 \sigma^2_0) \bar{u}^2 - 4 \sigma^2_0 \bar{u} \bar{u} + (\sigma^2 + 2 \sigma^2_0) \bar{u}^2 - i 4 \pi \sigma^2_0 \bar{u}^2 (\bar{u}^2 - \bar{u}^2)z_1}{\sigma^2_0 \bar{u}^2} \right\} \right. \]

(10a)

and \[ \langle I(\bar{u}_0) \rangle = \left(4 \pi G_0 / \xi^{1/2}\right)^2 \exp\left(-8 \pi^2 \bar{u}^2 / \sigma^2_0 \xi^2\right) \], where \( \xi = 16 \pi^2 + (\xi_1^2 / \sigma^2_0) (4 / \sigma^2_0 + 1 / \sigma^2_0) \). With Eqs. (10a) and (10b), we calculate \( \Gamma(\bar{u}_1,0) = \Gamma(\bar{u}_1) / \langle I(\bar{u}_1) \rangle \) numerically. In Fig. 3, we plot the ghost image for a triple slits object (with the width of each slit being 10\( \alpha \) and the separation between the two slits being 10\( \alpha \)) with \( z_1 = z_2 = 10 \)\( ^5 \) for different values of \( \sigma_0 \) and \( \sigma_0 \). Within the three slits, \( H(\bar{u}) = 1, 0.8, \) and 0.6, respectively, and is zero elsewhere.

From Fig. 3, we see no image for small \( \sigma_0 / z_1 \) (far field) [curves (a) and (b)]. Note that decreasing \( \sigma_0 \) does not help for small \( \sigma_0 / z_1 \). For a good quality image we need large \( \sigma_0 / z_1 \) (near field) [18, 19] and small \( \sigma_0 \). In curves (d) and (e), we note the formation of the image and the image edge of the middle slit spreads approximately from 3 to 4 and 4 to 6 (see the inset) with visibilities of 12\% and 7\%, respectively. When we have good quality image, the visibility is low which is in agreement with earlier studies [8, 20, 21]. Large-size slits result in low visibility.

For small \( \sigma_0 / z_1 \ll 1 \) (far field) we have HBT effect, but no thermal light ghost image. The difference can be explained as follows. In the HBT experiment, the measurement mainly differentiates between two values, HBT=1 or 0. This corresponds to one bit information. On the other hand, in the ghost image, we need to obtain the information of the whole object and this corresponds to a large amount of bits. The large amount of bits is processed together and one particular bit must not be influenced by other bits. For the curve (c) in Fig. 3, it is hard to say whether the image is formed. If we consider the three slits as three bits, we can conclude: “yes, we have three bits with good visibility in curve (c).”

Let us consider a very narrow slit for the object located at \( \bar{u} = \bar{a} \). The image measurement becomes the determination of one nonzero value at one location (and near by) and zero value at other locations, which is equivalent to the measurement in the HBT experiment to obtain one bit information. Setting \( z_1, \sigma_0 = \sigma_0 \) (valid in experiments) we have

\[ \frac{\langle \Gamma(\bar{u}_1,0) \rangle^2}{\langle I(\bar{u}_1) \rangle \langle I(\bar{u}_1) \rangle} = \exp\left(-\frac{(\bar{u}_1 - \bar{a})^2}{\sigma_0^2 + (\xi_1^2 / 4 \pi^2 \sigma_0^2)}\right) \]

(11)

The image of the very narrow slit is a Gaussian distribution with a width of \( \sigma_0^2 + (\xi_1^2 / 4 \pi^2 \sigma_0) \) [the same as Eq. (9a) for the HBT effect]. The width of the image for an ideal point at \( \bar{u}_{20} \) is limited by the width \( \sigma_0^2 + (\xi_1^2 / 4 \pi^2 \sigma_0^2) \). For small \( \sigma_0 / z_1 \ll 1 \), the ghost image of the very narrow slit can still be formed but with very bad quality (wide spread). This is the reason that the good image for small \( \sigma_0 / z_1 \) (far field) cannot be achieved even in the limit of \( \sigma_0 \rightarrow 0 \). While for a large \( \sigma_0 / z_1 \ll 0.2 \), not far field, small \( \sigma_0 \) may lead to small width (good image quality), a similar situation for the HBT experiment.

The accuracy of the image is limited by the width of the detector (no real point detector). Consequently, improving the quality of the image by increasing the size source is limited by the width of the detector. Also the width determines the possibility of detecting the HBT with large size of source, the width \( \lambda \sigma_0^2 + (\xi_1^2 / 4 \pi^2 \sigma_0^2) \) [see Eq. (9a)]. Within this limit, any size in the object equal to the width represents one bit. Currently, the width of the best detector is about 10\( \alpha \). In Fig. 4, we plot the images of objects contained one bit, two bits, and three bits for the detector with a width of 8\( \alpha \). For one bit object, the visibility is almost one, for the two bits and three bits objects, the visibility reduce to half.
It is clearly seen that Eq. (10) actually becomes a Gaussian-shape image, and the size of the object could be written by

$$\text{GL}(\bar{u}_1, \bar{u}_2 = 0) = \frac{|\Gamma(\bar{u}_1, 0)|^2}{\langle I(\bar{u}_1) \rangle \langle I(\bar{u}_2 = 0) \rangle} = \exp \left\{ -\frac{(\bar{u}_1 - \bar{a})^2}{\sigma_y^2} + \frac{\bar{z}_1^2}{4\pi^2 \sigma_x^2 \sigma_y^2} \right\}.$$  

(A3)

It is clearly seen that Eq. (A3) is similar to Eq. (9), which indicates that the image of an ideal pointlike object in GI experiment actually becomes a Gaussian-shape image, and the image size is limited by the propagation distance $\bar{z}_1$, the spatial coherence $\sigma_y$, and the light source size $\sigma_r$. Under the conditions of $\bar{z}_1$, $\sigma_y \gg \sigma_g$ (valid in experiments), Eq. (A3) could be approximately expressed by
\[
\Gamma(u_1, 0) = \frac{4\pi G_0}{\bar{\xi}^2 / \xi^{1/2}} \int d\vec{\bar{v}} H(\vec{\bar{v}}) \exp \left( \frac{i\pi \bar{u}_1^2 - i\pi \bar{v}^2}{\bar{\xi}^2} \right) \exp \left( - \frac{4\pi^2(\bar{\sigma}_1^2 + 2\bar{\sigma}_g^2)\bar{u}_1^2 - 4\bar{\sigma}_1^2\bar{u}_1\bar{v}_1 + (\bar{\sigma}_1^2 + 2\bar{\sigma}_g^2)\bar{v}_1^2}{\bar{\xi}^2} + \frac{16\pi^2(\bar{v}_2^2 - \bar{\bar{u}}_1^2)}{\bar{\xi}^2} \right) \\
\exp \left( - \frac{4\pi^2(\bar{\sigma}_1^2 + 2\bar{\sigma}_g^2)\bar{v}_1^2 - 4\bar{\sigma}_1^2\bar{v}_1\bar{v}_2 + (\bar{\sigma}_1^2 + 2\bar{\sigma}_g^2)\bar{v}_2^2}{\bar{\xi}^2} + \frac{16\pi^2(\bar{u}_2^2 - \bar{\bar{v}}_1^2)}{\bar{\xi}^2} \right) \\
\exp \left( - \frac{4\pi^2(\bar{\sigma}_1^2 + 2\bar{\sigma}_g^2)\bar{u}_2^2 - 4\bar{\sigma}_1^2\bar{u}_1\bar{v}_2 + (\bar{\sigma}_1^2 + 2\bar{\sigma}_g^2)\bar{v}_2^2}{\bar{\xi}^2} + \frac{16\pi^2(\bar{u}_1^2 - \bar{\bar{v}}_2^2)}{\bar{\xi}^2} \right) \right).
\]

Using Eqs. (A5)–(A7), we can obtain Eq. (12).
