(57) **ABSTRACT**

A method and system for decoding low density parity check ("LDPC") codes. An LDPC decoder includes a control unit that controls decoder processing, the control unit causing the decoder to process the blocks of a low density parity check ("LDPC") matrix out of order. A decoder embodiment may process the layers of the LDPC matrix out of order and/or perform partial state processing on out of order blocks of the LDPC matrix and/or generate R messages out of order.

LOW DENSITY PARITY CHECK DECODER FOR IRREGULAR LDPC CODES

CROSS-REFERENCE TO RELATED APPLICATIONS

The present application claims priority to U.S. provisional patent application Ser. No. 60/915,320 filed May 1, 2007, and entitled "Low Density Parity Check Decoder With On-the-Fly Computation" hereby incorporated herein by reference. The present application additionally claims priority to and incorporates by reference U.S. provisional patent application Ser. No. 60/988,680 filed Nov. 16, 2007, and entitled "Low Density Parity Check Decoder With On-the-Fly Computation."

BACKGROUND

Error correcting codes are used to automatically detect and correct errors in a received data signal. Generally, a data signal transmitter applies a selected encoding algorithm to a transmitted data signal. A receiver applies an appropriate decoder to determine whether the received signal was corrupted after transmission and to correct any errors detected. Low density parity check ("LDPC") codes are one of a variety of error correcting codes.

LDPC decoders operate near the Shannon limit. When compared to the decoding of turbo codes, low density parity check decoders require simpler computational processing, and they are more suitable for parallelization and low complexity implementation. Low density parity check decoders are applicable for error correction coding in a variety of next generation communication and data storage systems.

LDPC decoders require simpler computational processing than other error coding schemes. While some parallel low density parity check decoder designs for randomly constructed low density parity check codes suffer from complex interconnect issues, various semi-parallel and parallel implementations, based on structured low density parity check codes, alleviate the interconnect complexity.

Because of their superior performance and suitability for hardware implementation, LDPC codes are considered to be a promising alternative to other coding schemes in telecommunication, magnetic storage, and other applications requiring forward error correction.

SUMMARY

A variety of novel techniques for decoding low density parity check ("LDPC") codes are herein disclosed. The techniques disclosed present a number of advantages over known decoders, for example, embodiments allow for a reduction both in message storage memory and improved throughput. In accordance with at least some embodiments, a low density parity check code decoder comprises a control unit that controls decoder processing, the control unit causing the decoder to process the blocks of a low density parity check ("LDPC") matrix out of order.

In other embodiments, a method for decoding a low density parity check code comprises processing the blocks of a low density parity check ("LDPC") matrix out of order and providing a result of the processing to a user.

In other embodiments, a method for determining a processing sequence for a low density parity check ("LDPC") code comprises extracting parameters from an LDPC code matrix. A processing sequence of the blocks of the matrix is determined based, at least in part, on the parameters extracted from

the matrix. The determined processing sequence causes a decoder to process the blocks out of order.

In other embodiments, a computer program product comprises a computer useable medium having computer readable program code embodied therein. The computer readable program code comprises instructions that extract parameters from a low density parity check ("LDPC") matrix, and instructions that determine a processing sequence for decoding LDPC matrix based at least in part on the parameters extracted from the matrix. The determined processing sequence causes a decoder to process the blocks out of order.

Notation and Nomenclature

Certain terms are used throughout the following description and claims to refer to particular system components. As one skilled in the art will appreciate, entities may refer to a component by different names. This document does not intend to distinguish between components that differ in name but not function. In the following discussion and in the claims, the terms "including" and "comprising" and "e.g." are used in an open-ended fashion, and thus should be interpreted to mean "including, but not limited to . . .". The term "couple" or "couples" is intended to mean either an indirect or direct connection. Thus, if a first component couples to a second component, that connection may be through a direct connection, or through an indirect connection via other components and connections. The term "system" refers to a collection of two or more hardware and/or software components, and may be used to refer to an electronic device or devices, or a subsystem thereof. Further, the term "software" includes any executable code capable of running on a processor, regardless of the media used to store the software. Thus, code stored in non-volatile memory, and sometimes referred to as "embedded firmware," is included within the definition of software.

BRIEF DESCRIPTION OF THE DRAWINGS

In the following detailed description, reference will be made to the accompanying drawings, in which:

FIG. 1 shows a system comprising a low density parity check ("LDPC") decoder in accordance with various embodiments;

FIG. 2A shows a diagram of one embodiment of a check node unit ("CNU") of the LDPC decoder in accordance with various embodiments;

FIG. 2B shows a block diagram of a check node unit in accordance with various embodiments;

FIG. 3 shows an embodiment of a check node unit of a LDPC decoder that incorporates a dynamic shift mechanism for offset min-sum ("OMS") using the value-reuse property in accordance with various embodiments;

FIG. 4A shows a two phase message passing ("TPMP") decoder for regular array LDPC coded messages in accordance with various embodiments;

FIGS. 4B-4D show CNU arrays of the TPMP decoder in accordance with various embodiments;

FIG. 5 shows an LDPC decoder that uses layered decoding and an offset min-sum algorithm with block serial processing in accordance with various embodiments;

FIGS. 6A and 6B show a pipeline architecture for regular coded messages in accordance with various embodiments;

FIG. 6C shows pipeline architecture for irregular coded messages in accordance with various embodiments;

FIG. 7 shows a sub-block serial LDPC decoder in accordance with various embodiments;

FIG. 8 shows an LDPC decoder including layered decoding and two cyclic shifters in accordance with various embodiments;

FIG. 9 shows another LDPC decoder including layered decoding and two cyclic shifters in accordance with various 5 embodiments;

FIG. 10 shows an LDPC decoder that uses layered decoding and an offset min-sum algorithm with block parallel processing in accordance with various embodiments;

FIG. 11 shows a irregular block code suitable for out-of-order processing in accordance with various embodiments;

FIG. 12 shows an LDPC decoder that uses out-of-order processing for decoding irregular LDPC codes in accordance with various embodiments;

FIG. 13 shows another illustrative LDPC decoder that uses out-of-order processing for decoding irregular LDPC codes in accordance with various embodiments;

FIG. 14 shows another illustrative LDPC decoder that uses out-of-order processing for decoding irregular LDPC codes in accordance with various embodiments.

FIG. 15 shows an S matrix for an IEEE 802.16e rate 2/3 A code in accordance with various embodiments;

FIG. 16 shows an H_b base matrix for an IEEE 802.16e rate 2/3 A code in accordance with various embodiments;

FIGS. 17, 31, and 45 show a layer sequence for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 18, 32, and 46 show an S matrix in reordered form based on a selected layer sequence for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 19, 33, and 47 show an H_b base matrix for in reordered form based on a selected layer sequence for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 20, 34, and 48 show a check node degree vector for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 21, 35, and 49 show a variable node degree vector for schedule 1 schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 22, 36, and 50 show a block number matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 23, 37, and 51 show a circulant index matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 24, 38, and 52 show a dependent circulant index matrix for schedule 1 schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 25, 39, and 53 show a block column matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 26, 40, and 54 show a dependent layer matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 27, 41, and 55 show a dependent block matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 28, 42, and 56 show a shift matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments;

FIGS. 29, 43, and 57 show a delta shift matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments; and

FIGS. 30, 44, and 58 show a use channel value flag matrix for schedule 1, schedule 2, and schedule 3 processing, respectively, in accordance with various embodiments.

The drawings show illustrative embodiments that will be described in detail. However, the description and accompa-

nying drawings are not intended to limit the claimed invention to the illustrative embodiments, but to the contrary, the intention is to disclose and protect all modifications, equivalents, and alternatives falling within the spirit and scope of the appended claims.

DETAILED DESCRIPTION

FIG. 1 shows one embodiment of a system 100 comprising a low density parity check ("LDPC") decoder in accordance with various embodiments. System 100 generally includes a transmitter 102, and receiver 104. The receiver 104 comprises an I/O port 106, a processor 112, a memory 114, and an LDPC decoder 110. Transmitter 102 transmits signal 116 encoded using an LDPC code to provide forward error correction. Transmitter 106 may be any of a variety of devices adapted to provide an LDPC encoded signal 116 to the receiver 104. For example, transmitter 106 may be wireless transmitter, a wireline transmitter, an optical transmitter.

I/O port 106 is adapted to detect the signal 116 from transmitter 106 as received via the selected transmission medium. I/O port 116 may include any suitable protocol for receiving encoded signal 116 from transmitter 102. For example, I/O port 106 may incorporate an Ethernet protocol for network based communications or incorporate a wireless protocol, such as IEEE 802.11 or IEEE 802.16. The encoded signal 116 detected by the I/O port 106 is provided to the LDPC decoder 110. The LDPC decoder 110 decodes the encoded signal 116 to extract the signal encoded by the transmitter 102. The LDPC decoder 110 detects and corrects errors introduced into the signal 116 as the signal 116 traversed the channel 118. The LDPC decoder 110 preferably includes on-the-fly computation of LDPC codes as disclosed herein to optimize decoding performance, hardware resource utilization and power consumption.

Processor 112 may be any suitable computer processor for executing code stored in memory 114. Processor 16 controls operations of I/O port 12 by inputting data in the form of coded messages from remote computing system 20. Memory 14 may be any suitable type of storage for computer related data and/or programming which may be, for example, volatile memory elements, such as random access memory (RAM), dynamic random access memory (DRAM), static random access memory (SRAM), or FLASH memory.

Some embodiments of receiver 104 comprise a hardware implementation of the LDPC decoder 110. For example the LDPC decoder 110 may be implemented in an application specific integrated circuit ("ASIC") or a field programmable gate array ("FPGA"). Some embodiments of receiver 104 may provide the LDPC decoder 110 as software programming executed by processor 112. Some embodiments of receiver 104 may implement the LDPC decoder 110 as a combination of software programming executed by processor 112 and other electronic circuits.

While elements of system 100 are described in terms of data transmission and reception, system 100 is also applicable to other systems. For example, various embodiments may be applied to data storage systems where LDPC encoded data is stored on a storage medium (e.g., a magnetic disk). Thus, in such embodiments, the storage medium is represented by channel 118. Transmitter 102 provides media write systems, and receiver 104 provides media read systems.

LDPC codes are linear block codes described by an $m \times n$ sparse parity check matrix H . LDPC codes are well represented by bipartite graphs. One set of nodes, the variable or bit nodes correspond to elements of the code word and the other set of nodes, viz. check nodes, correspond to the set of parity check constraints satisfied by the code words. Typically the edge connections are chosen at random. The error correction capability of an LDPC code is improved if cycles of short

5

length are avoided in the graph. In an (r,c) regular code, each of the n bit nodes (b_1, b_2, \dots, b_n) has connections to r check nodes and each of the m check nodes (c_1, c_2, \dots, c_m) has connections to c bit nodes. In an irregular LDPC code, the check node degree is not uniform. Similarly the variable node degree is not uniform. The present disclosure focuses on the construction which structures the parity check matrix H into blocks of $p \times p$ matrices such that: (1) a bit in a block participates in only one check equation in the block, and (2) each check equation in the block involves only one bit from the block. These LDPC codes are termed Quasi-cyclic (“QC”) LDPC codes because a cyclic shift of a code word by p results in another code word. Here p is the size of square matrix which is either a zero matrix or a circulant matrix. This is a generalization of a cyclic code in which a cyclic shift of a code word by 1 results in another code word. The block of $p \times p$ matrix can be a zero matrix or cyclically shifted identity matrix of size $p \times p$. The Block LDPC codes having these blocks are referred as QC-LDPC codes. The block of $p \times p$ matrix can be a random permutation as in IEEE 802.3 Reed Solomon based LDPC codes. The present disclosure gives examples for QC-LDPC codes and it is straight forward for one skilled in the art to use the same embodiments for other Block LDPC codes with appropriate modification. To enable such modification, embodiments apply a permuter rather than a cyclic shifter.

An array low density parity check parity-check matrix for a regular quasi-cyclic LDPC code is specified by three parameters: a prime number p and two integers k (check-node degree) and j (variable-node degree) such that $j, k \leq p$. This is given by

$$H = \begin{bmatrix} I & I & I & \dots & I \\ I & \alpha & \alpha^2 & \dots & \alpha^{k-1} \\ I & \alpha^2 & \alpha^4 & \dots & \alpha^{2(k-1)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ I & \alpha^{j-1} & \alpha^{(j-1)2} & \dots & \alpha^{(j-1)(k-1)} \end{bmatrix}, \quad (1)$$

where I is a $p \times p$ identity matrix, and α is a $p \times p$ permutation matrix representing a single right cyclic shift (or equivalently up cyclic shift) of I. The exponent of α in H is called the shift coefficient and denotes multiple cyclic shifts, with the number of shifts given by the value of the exponent.

Rate-compatible array LDPC codes (i.e., irregular quasi-cyclic array LDPC codes) are modified versions of the above for efficient encoding and multi-rate compatibility. The H matrix of a rate-compatible array LDPC code has the following structure:

$$H = \begin{bmatrix} I & I & I & \dots & I & I & \dots & I \\ O & I & \alpha & \dots & \alpha^{j-2} & \alpha^{j-1} & \dots & \alpha^{k-2} \\ O & O & I & \dots & \alpha^{2(j-3)} & \alpha^{2(j-2)} & \dots & \alpha^{2(k-3)} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ O & O & \dots & \dots & I & \alpha^{(j-1)} & \dots & \alpha^{(j-1)(k-j)} \end{bmatrix}, \quad (2)$$

where O is the $p \times p$ null matrix. The LDPC codes defined by H in equation (2) have codeword length $N=kp$, number of parity-checks $M=jp$, and an information block length $K=(k-j)p$. A family of rate-compatible codes is obtained by successively puncturing the left most p columns, and the topmost p rows. According to this construction, a rate-compatible code within a family can be uniquely specified by a single parameter, for example, q with $0 < q \leq j-2$. To provide a wide range of

6

rate-compatible codes, j and p may be fixed, and different values for the parameter k selected. Since all the codes share the same base matrix size p; the same hardware decoder implementation can be used. Note that this specific form is suitable for efficient linear-time LDPC encoding. The systematic encoding procedure is carried out by associating the first N-K columns of H with parity bits, and the remaining K columns with information bits.

The block irregular LDPC codes have competitive performance and provide flexibility and low encoding/decoding complexity. The Block LDPC code is defined by a matrix H as:

$$H = \begin{bmatrix} P_{1,1} & P_{1,2} & \dots & P_{1,N_b} \\ P_{2,1} & P_{2,2} & \dots & P_{2,N_b} \\ \dots & \dots & \dots & \dots \\ P_{M_b,1} & P_{M_b,2} & \dots & P_{M_b,N_b} \end{bmatrix} = P^{H_b}, \quad (3)$$

where $P_{i,j}$ is one of a set of z-by-z cyclically right shifted identity matrices or a z-by-z zero matrix. Each 1 in the base matrix H_b is replaced by a permuted identity matrix while each 0 in H_b is replaced by a negative value to denote a z-by-z zero matrix. The shift coefficient matrix S for the H matrix of a rate 2/3 irregular LDPC code adopted for the IEEE 802.16e standard is shown in FIG. 15. Here $N_b=24$, $M_b=8$, $z=96$. The entry -1 in the matrix S corresponds to a z-by-z zero matrix (also called null matrix) in the H matrix. The entry 0 in the matrix S corresponds to a z-by-z identity matrix in the H matrix. The entry 3 in the matrix S corresponds to a z-by-z identity matrix cyclically right shifted by the shift amount 3. Each row in the S matrix represents a layer in the H matrix (i.e. the 1st row in the S matrix corresponds to the 1st layer (also called 1st block row) in the H matrix and so on). The binary base H_b is the same size as S. Each negative value of -1 is replaced with 0 and all other positive values (between 0 and z-1) are replaced with 1. Note that a code design usually starts with a binary base matrix H_b and the S matrix follows therefrom by optimizing the shift coefficient values. The base matrix H_b for the above LDPC code is shown in FIG. 16.

Considering now offset min-sum decoding of LDPC codes, assume binary phase shift keying (“BPSK”) modulation (a 1 is mapped to -1 and a 0 is mapped to 1) over an additive white Gaussian noise (“AWGN”) channel. The received values y_n are Gaussian with mean $x_n = \pm 1$ and variance σ^2 . The reliability messages used in a belief propagation (“BP”) based offset min-sum (“OMS”) algorithm can be computed in two phases: (1) check-node processing and (2) variable-node processing. The two operations are repeated iteratively until the decoding criterion is satisfied. This is also referred to as standard message passing or two-phase message passing (“TPMP”). For the ith iteration, $Q_{nm}^{(i)}$ is the message from variable node n to check node m, $R_{nm}^{(i)}$ is the message from check node m to variable node n, $M(n)$ is the set of the neighboring check nodes for variable node n, and $N(m)$ is the set of the neighboring variable nodes for check node m. The message passing for TPMP based on OMS is described in the following three steps to facilitate the discussion of turbo decoding message passing (“TDMP”) herein below:

7

Step 1. Check-Node Processing: for Each m and $n \in N(m)$,

$$R_{mm}^{(i)} = \delta_{mm}^{(i)} \max(\kappa_{mm}^{(i)} - \beta, 0), \quad (4)$$

$$\kappa_{mm}^{(i)} = |R_{mm}^{(i)}| = \min_{n' \in N(m) \setminus n} |Q_{n'm}^{(i-1)}|, \quad (5)$$

where β is a positive constant and depends on the code parameters. For (3, 6) rate 0.5 array LDPC code, β is computed as 0.15 using the density evolution technique. In general, for the irregular codes, embodiments apply the correction on variable node messages Q and the correction factor for each circulant is based on check node degree and variable node degree. In these embodiments, the Q message can be performed either by scaling down the messages with a scaling factor ($Q=Q \cdot \alpha$) or by applying an offset to the magnitude of Q message, ($Q=\text{sgn}(Q)\max(|Q|-\beta, 0)$)

The sign of check-node message $R_{mm}^{(i)}$ is defined as:

$$\delta_{mm}^{(i)} = \left(\prod_{n' \in N(m) \setminus n} \text{sgn}(Q_{n'm}^{(i-1)}) \right). \quad (6)$$

Step 2. Variable-Node Processing: for Each n and $m \in M(n)$:

$$Q_{nm}^{(i)} = L_n^{(0)} + \sum_{m' \in M(n) \setminus m} R_{m'n}^{(i)}, \quad (7)$$

where the log-likelihood ratio of bit n is $L_n^{(0)} = y_n$.

Step 3. Decision: for Final Decoding

$$P_n = L_n^{(0)} + \sum_{m \in M(n)} R_{mn}^{(i)}. \quad (8)$$

A hard decision is taken by setting $\hat{x}_n = 0$ if $P_n(x_n) \geq 0$, and $\hat{x}_n = 1$ if $P_n(x_n) \leq 0$. If $\hat{x}H^T = 0$, the decoding process is finished with \hat{x}_n as the decoder output; otherwise, repeat steps 1-3. If the decoding process doesn't end within predefined maximum number of iterations, it_{max} stop and output an error message flag and proceed to the decoding of the next data frame.

In TDMP, an array LDPC with j block rows can be viewed as a concatenation of j layers or constituent sub-codes. After the check-node processing is finished for one block row, the messages are immediately used to update the variable nodes (in step 2, above), whose results are then provided for processing the next block row of check nodes (in step 1, above). The vector equations for TDMP for array LDPC codes assuming that the H matrix has the structure in equation (1) are illustrated first. These equations are directly applicable to all other regular QC-LDPC codes (such as cyclotomic coset based LDPC). For rate compatible array LDPC codes and Block LDPC codes, minor modifications in the vector equations are necessary.

$$\vec{R}_{l,n}^{(0)} = 0, \vec{P}_n = \vec{L}_n^{(0)} \text{ [Initialization for each new received data frame]}, \quad (9)$$

$$\forall i = 1, 2, \dots, i_{\max} \text{ [Iteration loop]},$$

$$\forall l = 1, 2, \dots, j \text{ [Sub-iteration loop]},$$

$$\forall n = 1, 2, \dots, k \text{ [Block column loop]},$$

8

$$[\vec{Q}_{l,n}^{(i)}]^{s(l,n)} = [\vec{P}_n]^{s(l,n)} - \vec{R}_{l,n}^{(i-1)}, \quad (10)$$

$$\vec{R}_{l,n}^{(i)} = f([\vec{Q}_{l,n}^{(i)}]^{s(l,n)}, \forall n' = 1, 2, \dots, k), \quad (11)$$

$$[\vec{P}_n]^{s(l,n)} = [\vec{Q}_{l,n}^{(i)}]^{s(l,n)} + \vec{R}_{l,n}^{(i)}, \quad (12)$$

where the vectors $\vec{R}_{l,n}^{(i)}$ and $\vec{Q}_{l,n}^{(i)}$ represent all the R and Q messages in each $p \times p$ block of the H matrix, and $s(l,n)$ denotes the shift coefficient for the block in l^{th} block row and n^{th} block column of the H matrix. $[\vec{Q}_{l,n}^{(i)}]^{s(l,n)}$ denotes that the vector $\vec{Q}_{l,n}^{(i)}$ is cyclically shifted up by the amount $s(l,n)$ and k is the check-node degree of the block row. A negative sign on $s(l,n)$ indicates that it is a cyclic down shift (equivalent cyclic left shift). $f(\bullet)$ denotes the check-node processing, which embodiments implement using, for example, a Bahl-Cocke-Jelinek-Raviv algorithm ("BCJR") or sum-of-products ("SP") or OMS. Some embodiments use OMS as defined in equations (4)-(6). In an embodiment that processes a block row in serial fashion using p check-node units, as in equation (11), the output of the CNU will also be in serial form. As soon as the output vector $\vec{R}_{l,n}^{(i)}$ corresponding to each block column n in H matrix for a block row l is available, the output vector can be used to produce updated sum $[\vec{P}_n]^{s(l,n)}$ (equation (12)). The updated sum can be immediately used in equation (10) to process block row $l+1$ except that the shift $s(l,n)$ imposed on \vec{P}_n has to be undone and a new shift $s(l+1,n)$ has to be imposed. This re-shifting can be simply done by imposing a shift corresponding to the difference of $s(l+1,n)$ and $s(l,n)$.

Note that due to the slight irregularity in the array LDPC matrix defined in equation (2), each block row l has a node degree $j-l+1$. The variable-nodes in each block column n have a node degree equal to $\min(n,j)$. One way to simplify implementation is to assume that all the block rows have equal check-node degree and to set the check-node messages corresponding to null blocks in the H matrix to zero in order not to affect the variable-node processing. Similarly, the variable-node messages belonging to the null blocks are always set to positive infinity in order not to affect the check-node processing. For check-node update based on SP or OMS, the message with maximum reliability won't affect the CNU output. In the specific case of OMS, this is easily seen as the CNU magnitude is dependent on the two least minimum.

There are several null blocks in the Block LDPC codes defined by equation (3). So the above method for dealing with irregularity introduces significant idle clock cycles. Some embodiments deal with this check-node irregularity by setting the check-node degrees in a CNU processor unit based on the block row that is being processed. In addition, out-of-order processing is enforced in the generation of R messages as explained below.

The micro-architecture of an embodiment of a serial CNU for OMS is now considered. For each check node m , $|R_{mm}^{(i)}| \forall n \in N(m)$ takes only two values, which are the two minimum of input magnitude values. Since $\forall n \in N(m)$, $\delta_{mm}^{(i)}$ takes a value of either $+1$ or -1 and $|R_{mm}^{(i)}|$ takes only 2 values, equation (4) gives rise to only three possible values for the whole set, $R_{mm}^{(i)} \forall n \in N(m)$. In a very-large-scale integration ("VLSI") implementation, this property significantly simplifies the logic and reduces the memory.

FIG. 2A shows an embodiment of a Check-Node Unit ("CNU") micro-architecture 200 for OMS that applies the value re-use property. FIG. 2B shows the block diagram of the same. The exemplary micro-architecture is considered as applied to a (5, 25) code. In the first 25 clock cycles of the

check-node processing, incoming variable messages (Q 204) are compared with the two up-to-date least minimum numbers (partial state, PS) 206, 208 to generate the new partial state, M1 206 which is the first minimum value, M2 208 which is the second minimum value, and the index of M1 224. The final state (FS) is then computed by offsetting the partial state. It should be noted that the final state includes only M1, -M1, +/-M2 with offset correction applied to each. M1_M2 finder 202 computes the two least numbers, according to the incoming data 204 and the current minimum numbers 206, 208 stored in partial state. The offset module 210 applies the offset correction, and stores the results in the Final State module 212. R selector 216 then assigns one out of these 3 values, based on the index of M1 218 and the sign of R message generated by sign exclusive “or” (“XOR”) logic, equation (6), to the output R messages. While the final state has dependency on offset correction, the offset is dependent on the completion of partial state 214. In operation, the final state 212 and partial state 214 will operate on different check-nodes. The serial CNU 200 finds the least two minimum numbers 206, 208 with 2 comparators 200, 222 in a serial fashion and reduces the number of offset-correction computations from k to 2. Normally, CNU processing is done using signed magnitude arithmetic for equations (4)-(6). Variable-node unit (“VNU”) processing of equation (7) is done in 2’s complement arithmetic. Such processing requires 2’s complement to signed magnitude conversion at the inputs of CNU and signed magnitude to 2’s complement conversion at the output of CNU. In various embodiments, however, 2’s complement is applied to only 2 values instead of k values at the output of CNU. The value re-use property also reduces the memory requirement significantly. Conventionally, the number of messages each CNU stores is equal to the number of edges it has, that is k. In some embodiments, only four units of information are needed: the three values that $R_{mn}^{(i)}$ may take (M1, -M1, +/-M2 all with offset correction) and the location of $M1_{(m)}^{(i)}$ (index of M1). A check-node message to the VNU is then readily chosen by multiplexing. Some embodiments to store only M1, M2, and the index of M1 to effectuate further savings in the memory required to store the Final State (FS).

FIG. 4A shows a low density parity check decoder 400 for TPMP and OMS for regular array LDPC codes in accordance with various embodiments. Specifically, in this example, a decoder for an array LDPC code of length 1830 with the circulant matrix size of 61 is shown. The check node processing unit array is composed of 3 sub-arrays 402, 406, 408. Each sub-array (as shown in FIG. 4B) contains 61 serial CNUs (e.g., FIG. 2 200) which compute the partial state for each block row to produce the check-node messages for each block column of H. CNU array block row 1 402 is an array of 61 simple CNUs 200.

Cyclic shifters, generally, consume approximately 10%-20% of chip area based on the decoder’s parallelization and constitute the critical path of the decoder. If all the block rows are assigned to different computational unit arrays of CNUs and serial CNU processing across block rows is employed, then embodiments use constant wiring to achieve any cyclic shift as each subsequent shift can be realized using the feedback of a previous shifted value. Embodiments thus eliminate both the forward router between CNU and VNU and the reverse router between VNU and CNU. This is possible because block-serial processing is employed and array codes have a constant incremental shift in each block row. For the first block row, the shift and incremental shift is 0. For the second block row, the shifts are [0, 1, 2, . . .] and the incremental shift is 1. For the third block row, the shifts are [0,

2, . . .] and the incremental shift is 2. In this TPMP architecture embodiment, the check node messages in the H matrix are produced block column wise so that all the variable messages in each block column can be produced on the fly. These variable-node messages can be immediately consumed by the partial state computation sub-units in the CNUs. Such scheduling results in savings in message passing memory that is needed to store intermediate messages. The savings in message passing memory due to scheduling are 80%, in some cases, as embodiments need to store only the sign bits of variable node messages. Forward and reverse routers are eliminated, reducing the number of multiplexers required.

CNU array block rows 2 and 3 (406, 408) are composed of dynamic CNUs 300. The variable node processing array 404 is composed of 61 parallel VNU units which can process 3×61 messages at each clock cycle. The sign bits will be stored in a first-in-first-out memory (“FIFO”) (implemented as RAM), however, there is no need to subject these values to shifts as these values are not modified in check node processing partial state processing. In the array 402 of simple serial CNU 200 that is designed to do check node processing for first block row in H matrix, the check node processing for each row in H matrix is done such that all the comparisons are performed locally within one CNU to update the partial state each clock cycle and transfer the partial state to final state d_c once every cycle.

As shown in FIG. 3, in the dynamic CNU 300, the M1_M2 finder 302 and offset block 306 receive partial state input from another CNU rather than partial state block 304. The final state block 310 receives input from both the offset block 306 and another CNU 300. Accordingly, the partial state block 304 and final state block 310 provide output to other CNUs 300. In CNU array 406 (shown in FIG. 4C), designed for the second block row in an H matrix, CNU122 gets its partial state from CNU121, CNU121 gets its partial state from CNU120 and so on. The array of dynamic CNU 408 (shown in FIG. 4D) is designed for the third block row in an H matrix such that the connection between partial state registers among various units achieve cyclic shifts of [0, 2, . . . , 58], thus CNU125 gets its partial state from CNU 123. A similar principle is applied when making connections for the final state in the CNU array to achieve reverse routing (i.e., CNU123 gets its partial state from CNU183 and CNU 182).

Initially the variable messages are available in row wise as they are set to soft log-likelihood information (“LLR”) of the bits coming from the channel. Q Init 410 is a RAM of size 2N and holds the channel LLR values of two different frames. Q Init 410 can supply p intrinsic values to the VNUs each clock cycle. The data path of the embodiment is set to 5 bits to provide the same bit error rate (“BER”) performance as that of a floating point sum of products algorithm with 0.1-0.2 dB SNR loss. Each iteration takes $d_c + 3$ clock cycles. For (3, 30) code this results in 6×33 clock cycles to process each frame when a maximum number of iterations set to 6. For (3, 6) code this results in 20×9 clock cycles to process each frame when the number of iterations is set to 20.

FIG. 5 shows a turbo decoding message passing decoder 500 in accordance with various embodiments. As a matter of simplification, the present disclosure illustrates the architecture for a specific structured code: a regular array code of length 1525 described by equation (1), $j=5$, $k=25$ and $p=61$. One skilled in that art will understand that the example can be easily generalized to any other structured code. The functionality of each block in the architecture is explained below. In discussing the present and subsequent embodiments, a distinction is made regarding the various R messages presented. Assume, for example, that layer l and iteration i are presently

11

being processed. The next layer to be processed in the present iteration i has R messages that were computed in the previous iteration. These messages are termed “R old” messages. The layer presently being processed in the present iteration has R messages that were computed in the previous iteration. These messages are termed “R prev” messages. The R messages that are being computed for the present layer in the present iteration are termed “R new” messages.

The CNU array **502** is composed of p computation units (CNU **200** described supra) that compute the partial state for each block row to produce the R messages **526** in block serial fashion. The final state of previous block rows, in which the compact information for CNU messages is stored, is needed for TDMP. The final state information is stored in register banks **504**. There is one register bank **504** of depth $j-1$, which is 4 in this example, connected with each CNU **200**. Each final state register bank **504** is the same as the final state register bank **226** in the CNU **200**. In addition to the shifted Q messages **506**, the CNU array **502** takes as input the sign information **508** from previously computed Q messages in order to perform an R selection operation. The R sign bits are stored in sign FIFO **510**. The total length of sign FIFO **510** is k and each block row has p one bit sign FIFOs. Embodiments employ $j-1$ of such FIFO banks **510** in total.

Quantity p R select units **512** are used for generation of R old **516**. An R select unit **512** generates the R messages for $25(=k)$ edges of a check-node from three possible values stored in a final state register associated with that particular check-node in a serial fashion. Its functionality and structure is the same as the block denoted as R select **216** in CNU **200**. The R select unit **512** can be treated as a de-compressor of the check node edge information which is stored in compact form in FS registers **504**. The generation of R messages **516** for all the layers in this way amounts to substantial memory savings.

The shifter **514** is constructed as cyclic up logarithmic shifter to achieve the cyclic shifts specified by the binary encoded value of the shift. The logarithmic shifter **514** is composed of $\log_2(p)$ stages of p switches. Since cyclic down shift is also needed in the operation of the decoder, cyclic down shift by u can be simply achieved by doing cyclic up shift with $p-u$ on the vector of size p .

The decoding operation proceeds as per the vector equations (9)-(12). In the beginning of the decoding process, P vector **520** is set to receive channel values in the first k clock cycles (i.e. the first sub-iteration) as the channel values arrive in chunks of p , while the output vector **516** of R select unit **512** is set to a zero vector. In some embodiments, the multiplexer array **518** at the input of cyclic shifter **514** is used for this initialization. In other embodiments, a multiplexer at the input of Q message FIFO **524** selects channel values for FIFO storage during initialization.

The CNU array **502** takes the output of the cyclic shifter **514** serially, and the partial state stage **214** operates on these values. After k clock cycles, partial state processing will be complete and the final state stage **212** in CNU array **502** will produce the final state for each check-node in 2 clock cycles. Subsequently, R select unit **216** within each CNU unit **200** starts generating k values of check-node messages in serial fashion. The CNU array **502** thus produces the check-node messages in a block serial fashion as there are p CNUs **200** operating in parallel. The P vector **520** is computed by adding the delayed version of the Q vector (which is stored into a FIFO SRAM **524** until the serial CNU produces the output) to the output vector R **526** of the CNU **502**. Note that the P vector **520** that is generated can be used immediately to generate the Q vector as the input to the CNU array **502** as CNU array **502** is ready to process the next block row. This is possible

12

because CNU processing is split into three stages as shown in the pipeline diagrams **6A-6B** and partial state stage **214** and final state stage **212** can operate simultaneously on two different block rows. The P message vector **520** will undergo a cyclic shift by the amount of difference of the shifts of the block row that is being processed, and the block row that was last processed. This shift value can be either positive or negative indicating respectively that the cyclic shifter needs to perform an up shift or down shift. The R message **516** is subtracted from the shifted P sum message to produce the shifted version of the Q message **506**.

The snapshot of the pipeline of the decoder **500** is shown in FIGS. **6A** and **6B**. FIG. **6A** is detailed diagram and FIG. **6B** is a simple diagram. In this illustration, the partial state stage **214** in CNU **200** is operating on the 2^{nd} block row from clock cycles labeled as 0 to 24 (note that these numbers will not denote the actual clock numbers as the snapshot is shown in the middle of the processing). Final state stage **212** in CNU **200** can not start until the end of PS processing, that is clock cycle **25**. As soon as the FS is done in clock cycle **26**, R select **216** is able to select the output R messages, and P and Q message processing starts. With the first block of Q message ready, partial state for next block row can be started immediately. Note that all the logic blocks (other than the storage elements) are active over 90% of the time. The only exception is the offset module **226**, which is composed of two 5-bit adders, in each CNU **200**. The overall proportion of all the CNU FS logic **212** in the overall decoder **500** is less than 4%. The control unit **528** contains the information of array code parameters such as i, k, q —these parameters can be changed to support multi-rate decoding.

A family of rate-compatible codes is obtained by successively puncturing the left most p columns and the topmost p rows in the H matrix defined in equation (2) q times. Changing q from 0 to $3(=j-2)$ gives the code rates of 0.8 to 0.909. Changing k values from 15 to 61 while fixing $j=5$ results in code rates from 0.666 to 0.91. The Q FIFO needs to be of maximum depth p as the k can take a maximum value equal to p . Note that for Block LDPC codes, the Q FIFO may be replaced with a random access memory of the same size, as shown in FIG. **12**. In addition out-of-order processing is employed on R selection for R new to account for the irregularity of Block LDPC codes

Note that the throughput of the architecture is increased by increasing p of the code, and scaling the hardware accordingly. While the complexity of computational units scales linearly with p , the complexity of the cyclic shifter increases with the factor $(p/2)\log_2 p$. So, it is necessary to change the architecture for large values of p . Alternatively it may be desirable to have low parallelization in low throughput applications. To suit this requirement, minor changes in the proposed architecture are necessary. Assume that the desired parallelization is $M < p$. For ease of implementation, choose M close to a power of 2. The cyclic shifter needed is $M \times M$. Since a $p \times p$ cyclic shift is to be achieved with consecutive shifts of $M \times M$, it is necessary for the complete vector of size p to be available in M banks with the depth $s = (\text{ceil}(p/M))$ and shifting is achieved in part by the cyclic shifter, and in part by address generation. In such embodiments, all the CNU and variable node processing is done in a time division multiplexed fashion for each sub-vector of length M , so as to process the vector of size p to mimic the pipeline in FIG. **6A, 6B**. Such processing is referred to as sub-block serial processing.

FIG. **7** shows a sub-block serial LDPC decoder in accordance with various embodiments. The final state array **504**, R select unit **512**, and sign bit array **510** are as described above

13

in relation to decoder 500. The CNU array 702 includes M CNUs 200, where $M < p$, resulting in a reduction of CNU array logic as described above. Because CNU array 702 processes sub-blocks rather than blocks, the results of sub-block processing, i.e., intermediate block processing partial state data, is stored in memory 730. These intermediate results are read into the CNU array as block processing progresses.

An $M \times M$ permuter (i.e., cyclic shifter) 714 is used as described above. As explained, shifting of the vector P is accomplished by a combination of permuter 714 shifts and addressing of P buffer 718.

FIG. 8 shows an LDPC decoder 800 including layered decoding and two cyclic shifters in accordance with various embodiments. The vector equations applicable to this embodiment comprise the following:

$$\vec{R}_{l,n}^{(0)} = 0, \vec{P}_n = \vec{L}_n^{(0)} \text{ [Initialization for each new received data frame],} \quad (13)$$

$$\forall i = 1, 2, \dots, i_{max} \text{ [Iteration loop],}$$

$$\forall l = 1, 2, \dots, j \text{ [Sub-iteration loop],}$$

$$\forall n = 1, 2, \dots, k \text{ [Block column loop],}$$

$$[\vec{Q}_{l,n}^{(i)}]^{S(l,n)} = [\vec{P}_n]^{S(l,n)} - \vec{R}_{l,n}^{(i-1)}, \quad (14)$$

$$\vec{R}_{l,n}^{(i)} = f([\vec{Q}_{l,n}^{(i)}]^{S(l,n)}, \forall n' = 1, 2, \dots, k), \quad (15)$$

$$\vec{P}_n = \vec{P}_n + [\vec{R}_{l,n}^{(i)} - \vec{R}_{l,n}^{(i-1)}]^{-S(l,n)}, \quad (16)$$

where the various terms are as defined in regard to equations (9)-(12) above. The decoder 800 is illustrated as configured for the same code used to illustrate decoder 500, a regular array code of length 1525 described by equation (1), $j=5$, $k=25$ and $p=61$.

Decoder 800 includes a CNU array 502 and a sign FIFO array 510 as described above in regard to decoder 500. The final state array 804 is similar to array 504, but includes five rather than 4 register banks. Two R select units 812, 813 are included as are a cyclic down shifter 814 and a cyclic up shifter 815. The R select units 812, 813 are functionally equivalent to R selector 512 described above. Sign FIFO 824 delays application of sign bits to R select unit 813. In accordance with equation (14), shifted Q message 806, input to CNU array 502, is produced by subtracting the R old message 816 provided by the R selector unit 812 from the P message 820 shifted by the cyclic up shifter 815. The P message 820 is constructed by adding the difference of the R new message 826 from the CNU array 502 and the R prey message 832 provided by R selector unit 813 shifted by cyclic down shifter 814 to the P message 828 provided by P memory 830.

At the beginning of the decoding process, multiplexer 518, coupled to the input of the P memory 830, is set to provide channel values to P memory 830. The channel values serve as initial P messages to initialize the decoder 800.

FIG. 9 shows another LDPC decoder 900 including layered decoding and two cyclic shifters in accordance with various embodiments. The vector equations applicable to this embodiment comprise the following:

$$\vec{R}_{l,n}^{(0)} = 0, \vec{P}_n = \vec{L}_n^{(0)} \text{ [Initialization for each new received data frame],} \quad (17)$$

$$\forall i = 1, 2, \dots, i_{max} \text{ [Iteration loop],}$$

$$\forall l = 1, 2, \dots, j \text{ [Sub-iteration loop],}$$

$$\forall n = 1, 2, \dots, k \text{ [Block column loop],}$$

14

$$[\vec{Q}_{l,n}^{(i)}]^{S(l,n)} = [\vec{P}_n]^{S(l,n)} - \vec{R}_{l,n}^{(i-1)}, \quad (18)$$

$$\vec{R}_{l,n}^{(i)} = f([\vec{Q}_{l,n}^{(i)}]^{S(l,n)}, \forall n' = 1, 2, \dots, k), \quad (19)$$

$$[\vec{P}_n]^{S(l,n)} = [\vec{Q}_{l,n}^{(i)}]^{S(l,n)} + \vec{R}_{l,n}^{(i)}, \quad (20)$$

where the various terms are as defined in regard to equations (9)-(12) above. The decoder 900 is illustrated as configured for the same code used to illustrate decoders 500 and 800, a regular array code of length 1525 described by equation (1), $j=5$, $k=25$ and $p=61$.

Decoder 900 includes a CNU array 502 and a sign FIFO array 510 as described above in regard to decoder 500. The final state array 804, R select units 812, 813, cyclic shifters 814, 815, and sign FIFO 824 are as described above in regard to decoder 800. In accordance with equation (18), shifted Q message 906, input to CNU array 502, is produced by subtracting an R old message 932 provided by the R selector unit 812 from the shifted P message 920. The P message 920 is constructed (equation (20)) by adding the difference of the R new message 926 from the CNU array 502 and the R prev message 916 provided by R selector unit 813 to the P message provided by P memory 830 shifted by cyclic up shifter 900. The decoder 900 is initialized by selecting channel values for storage in P memory 830 using multiplexer 518 as described above in regard to decoder 800.

FIG. 10 shows an LDPC decoder 1000 that uses layered decoding and an offset min-sum algorithm with block parallel processing in accordance with various embodiments. As does decoder 500, embodiments of decoder 1000 apply vector equations (9)-(12). The difference between the two decoders, 500 and 1000, being that decoder 1000 processes all the block columns of M (where, $M \leq p$) rows in a layer in one clock cycle. In decoder 500, which employs block serial processing, one block column is processed for p rows. In decoder 700, which employs sub-block serial processing, one block column is processed for M rows, where $M \leq p$. Thus, embodiments of decoder 1000 use a check node unit array 1002 that can find M1 and M2 in one or two clock cycles when all the inputs to CNU are present at the same time. For the irregular block LDPC codes, the TDMP algorithm can be described with equations (21)-(24):

$$\vec{R}_{l,n}^{(0)} = 0, \vec{P}_n = \vec{L}_n^{(0)} \text{ [Initialization for each new received data frame],} \quad (21)$$

$$\forall i = 1, 2, \dots, i_{max} \text{ [Iteration loop],}$$

$$\forall l = 1, 2, \dots, j \text{ [Sub-iteration loop],}$$

$$\forall n = 1, 2, \dots, k \text{ [Block column loop],}$$

$$[\vec{Q}_{l,n}^{(i)}]^{S(l,n)} = [\vec{P}_n]^{S(l,n)} - \vec{R}_{l,n}^{(i-1)}, \quad (22)$$

$$\vec{R}_{l,n}^{(i)} = f([\vec{Q}_{l,n}^{(i)}]^{S(l,n)}, \forall n' = 1, 2, \dots, k), \quad (23)$$

$$[\vec{P}_n]^{S(l,n)} = [\vec{Q}_{l,n}^{(i)}]^{S(l,n)} + \vec{R}_{l,n}^{(i)}, \quad (24)$$

where the vectors $\vec{R}_{l,n}^{(i)}$ and $\vec{Q}_{l,n}^{(i)}$ represent all the R and Q messages in each non-zero block of the H matrix, $s(l,n)$ denotes the shift coefficient for the l^{th} block row and n^{th} non-zero block of the H matrix (note that null blocks in the H matrix need not be processed); $[\vec{R}_{l,n}^{i-1}]^{S(l,n)}$ denotes that the vector $\vec{R}_{l,n}^{i-1}$ is cyclically shifted up by the amount $s(l,n)$, and k is the check-node degree of the block row or the layer. A negative sign on $s(l,n)$ indicates that it is cyclic down shift

(equivalent cyclic left shift). $f(\bullet)$ denotes the check-node processing, which can be performed using BCJR, SP or MS.

To accommodate the irregularity in block LDPC codes, the R selection unit for selecting R old ($\vec{R}_{l,n}^{(i-1)}$ in equation (22)) and partial state processing are executed in linear order for the current layer (i.e. first non-zero block, second non-zero block, etc. in a layer). The order of R generation for R new processing ($\vec{R}_{l,n}^{(i)}$ in equation (23)), however, is determined by the non-zero blocks of the next layer to be processed because $\vec{Q}_{l,n}^{(i)}$ in equation (22) of the next layer is dependent on $[\vec{P}_n]$ in equation (24) of the last layer that is updated (this is not necessarily the previous layer in the H matrix because of the irregularity of the H matrix) which in turn depends on $\vec{R}_{l,n}^{(i)}$ in equation (23) of the previous layer. Furthermore, since the check node degree of each layer in Irregular Block codes may vary widely, it is not efficient to process each layer for a number of clock cycles equal to the maximum check-node degree. Additionally, data dependencies may necessitate that the processing of the next layer be stalled. To address these inefficiencies, embodiments apply out-of-order processing on R new generation. The R select unit for R new may operate on any of the previous layers. R generation is independent of PS or FS processing, so, out-of-order R message generation imposes no any additional restriction on the architecture.

Based on the desired hardware implementation objectives, for example, the number of pipeline stages required in a hardware implementation without stall cycles and/or reducing the number of memory accesses, embodiments optimize the processing order of the layers in the H matrix. Such processing is referred to as reordering of layers. In an H matrix having 8 layers, there are factorial of 8 combinations to choose for the processing order. Embodiments generate a permutation such that two adjacent layers have many independent circulants and then generate the decoder scheduling parameters and determine if the desired processing objective is met. If the desired processing objective is not met, embodiments continue testing another permutation. A good optimized layer sequence is generally determined within the first 1000 or a limited set of trails. Note that reordering the H matrix does not change the LDPC code specification, thus, embodiments can decode data that is encoded by the original H matrix.

Embodiments first extract several code related parameters that aid in scheduling the decoding process. These parameters may be extracted from the S matrix, the H matrix or the base matrix H_b . Some embodiments use the base matrix H_b and the S matrix to obtain the following parameters. Based on the desired objectives (e.g., reducing pipeline stalls), embodiments optimize the processing order of the layers in the H matrix. For each ordering, embodiments generate the following parameters and see if the desired objective is met.

Check node degree of each layer in H matrix: This is defined as the number of entries in the corresponding row of S matrix, whose value is not equal to -1. This also can be defined as the number of non-zero entries in the corresponding row of the H_b matrix as shown in below equation (25),

$$dc(l) = \sum_{n=1}^{N_b} H_b(l, n). \quad (25)$$

Variable node degree of each block column in H matrix: This is defined as the number of entries in the corresponding column of the S matrix, whose value is not equal to -1. This also

can be defined as the number of non-zero entries in the corresponding column of the H_b matrix as shown below in equation (26),

$$dv(n) = \sum_{l=1}^{M_b} H_b(l, n) \quad (26)$$

5 Circulant size, z: The size of the block or sub-block or circulant in the H matrix.

Block Number, bn: Each non-zero circulant in each layer of the H matrix is identified with a unique number.

15 Circulant Index, ci: Each non-zero circulant in the entire H matrix is identified with a unique number.

Block column bc: This is the block column of the specified non-zero circulant in the H matrix.

20 Dependent layer dl: This is the layer that supplies the last updated information of P message to the specified non-zero circulant.

Dependent non-zero circulant is the non-zero circulant that supplies the last updated information of P message to the specified non-zero circulant. The specified and the dependent circulant share the same block column.

25 Dependent block db: This is the block number of the non-zero circulant in the dependent layer (DL) that supplies the last updated information of P message to the specified non-zero circulant.

30 Dependent Circulant Index dci: This is the circulant index of the non-zero circulant in the dependent layer (DL) that supplies the last updated information of P message to the specified non-zero circulant.

35 Shift Matrix sm: This is the shift coefficient of the specified non-zero circulant.

Delta Shift Matrix dsm: This is the delta shift coefficient of the specified non-zero circulant. Delta Shift Matrix is equal to the difference of the sm of the specified non-zero circulant and sm of the dependent non-zero circulant.

40 Use Channel Value Flag ucvf: This is the flag of the specified non-zero circulant. If this flag is 1, it indicates that this is the first non-zero circulant that is updated in its block column bc. If this flag is 1 and the iteration is the first iteration, then the specified non-zero circulant gets the channel LLR value as a P message. In other cases, the non-zero circulant gets an updated P message from other non-zero circulants in its block column.

45 The matrices for the above variables for the complete H matrix are denoted with capital and italics of the same name.

50 Note that some of the matrices need not be stored for some decoder configurations and decoder schedules. Embodiments apply the correction on variable node messages Q and the correction factor for each circulant is based on check node degree and variable node degree. These correction factors are stored in a matrix BETA that is indexed by check node degree and variable node degree of the specified circulant.

55 The following pseudo-code shows embodiments of 3 algorithms for extracting scheduling parameters from a given H matrix specified by the matrices S and H_b .

60 Parameter Extraction Algorithm Part 1:

The matrix Cl_temp are initialized to zero matrices of size $M_b \times dc_{max}$. Due to the irregularity in check node degree (i.e., when $dc(l) < dc_{max}$), some of the last entries in some of the rows in these matrices remain at zero. As an example, $B(i,j)$ represents the value in the B matrix at ith row and jth column.

17

```

BN_temp = zeros(Mb, Nb);
CI_temp = zeros(Mb, dcmax);
ci = 0;
for l = 1: Mb BEGIN
    bn = 0;
    for n = 1: Nb BEGIN
        if Hb(l, n) ≠ 0 BEGIN
            ci = ci + 1;
            bn = bn + 1;
            BN_temp(l, n) = bn;
            CI_temp(l, bn) = ci;
        END
    END
END
END

```

Parameter Extraction Algorithm Part II:

```

DC = zeros(Mb);
BN = zeros(Mb, dcmax);
BC = zeros(Mb, dcmax);
DL = zeros(Mb, dcmax);
DB = zeros(Mb, dcmax);
CI = zeros(Mb, dcmax);
DCI = zeros(Mb, dcmax);
DV = zeros(Nb);
SM = -1 * zeros(Mb, dcmax);
DSM = -1 * zeros(Mb, dcmax);
for l = 1: Mb BEGIN
    bn = 0;
    DC(l) = dc(l);
    for n = 1: Nb BEGIN
        if Hb(l, n) ≠ 0 BEGIN
            bn = bn + 1;
            pl = l - 1, if l > 1
                = Mb, if l = 1
            while Hb(pl, n) == 0 BEGIN
                pl = pl - 1, if pl > 1
                    = Mb, if pl = 1
            END
            dl = pl;
            db = BN_temp(dl, n);
            BC(l, bn) = n;
            BN(l, bn) = bn;
            DL(l, bn) = dl;

```

18

-continued

```

(27) DB(l, bn) = db;
    CI(l, bn) = CI_temp(l, bn);
    5 DCI(l, bn) = CI_temp(dl, db);
    SM(l, bn) = S(l, n);
    DSM(l, bn) = S(l, n) - S(dl, n);
    10 if DSM(l, bn) < 0 BEGIN DSM(l, bn) = z + S(l, n) - S(dl, n);
    END
    DV(n) = dv(n);
    END
    15 END
    END
    20 Parameter Extraction Algorithm Part III:

```

```

Embodiments also extract the Use Channel Value Flag (UCVF).
UCVF = zeros(Mb, dcmax);
25 for n = 1: Nb BEGIN
    for l = 1: Mb BEGIN
        if Hb(l, n) ≠ 0 BEGIN
            UCVF(l, BN_temp(l, n)) = 1;
            BREAK THE INNER FOR LOOP AND GO BACK
            TO OUTER FOR LOOP
        END
    END
    30 END
    END
    END

```

FIG. 15 shows an S matrix for an IEEE 802.16e rate 2/3 A code. There are 8 rows and 24 columns in the S matrix. Thus, there are 8 layers (or 8 block rows) and 24 block columns in the corresponding H matrix. The circulant size is 96. Zero circulants are denoted with -1 in the S matrix. So, the H matrix has a zero circulant (i.e. all zero matrix with size 96×96) corresponding to each -1 entry in S matrix. A zero circulant in the H matrix corresponds to a 0 entry in the H_b matrix. Assume that processing is performed in layer sequence (i.e., in layer 1, 2, . . . 8) in each iteration.

The following are the parameters of the circulant **1508** marked with the circle (denote this as the specified circulant):

The specified circulant **1508** belongs to 3rd layer.

This is the first non-zero circulant in this layer. So, the block number bn for the specified circulant **1508** is 1.

The circulant index ci for this specified circulant **1508** is 21.

The block column bc for this specified circulant **1508** is 3. This specified circulant **1508** takes the updated P message from the circulant **1506** marked with the rectangle. So, circulant **1506** is the dependent circulant of the circulant **1508**.

The dependent circulant **1506** has a circulant index ci of 11. So, the dependent circulant index dci of the circulant **1508** is 11.

The layer of the dependent circulant **1506** is 2. So the dependent layer dl of the circulant **1508** marked with the circle is 2.

The block number of the dependent circulant **1506** is 1. So, the dependent block number db of the specified circulant **1508** is 1.

The shift coefficient of the specified circulant **1508** is 12. Thus, the shift matrix coefficient sm of the specified circulant **1508** is 12. The H matrix has a circulant (i.e. identity matrix of size 96×96 that is cyclically shifted

right by the amount 12) corresponding to 12 entry **1508** in the S matrix. Note that a non-zero circulant in the H matrix corresponds to 1 entry in the H_b matrix.

The shift coefficient of the dependent circulant **1506** is 1. So, the delta shift matrix coefficient dsm of the specified circulant **1508** is $12-1=11$.

The specified circulant **1508** is the second non-zero circulant in the 3rd block column. Since the specified circulant **1508** is NOT the first non-zero circulant in its block column, the specified circulant takes the updated P message from the dependent circulant **1506** in all the iterations. Therefore, the use channel value flag ucvf of the specified circulant **1508** is 0.

Referring now to FIG. 11, an irregular block code **1100** suitable out-of-order processing is shown. Embodiments perform out-of-order processing at any of several levels of complexity. An embodiment may perform R selection out of order so that the R message can be timely provided for partial state processing of a subsequent layer. Thus, while processing code **1100** the R message for block **1102** of layer 1 may not be selected until needed for partial state processing of the block **1104** of layer 2. The decoder scheduling parameters that facilitate the decoder functionality for this schedule (referred to herein as “schedule 1”) are listed in FIG. 17 to FIG. 30.

An embodiment can reorder block processing such that while processing layer 2, the blocks of layer 2 which depend on layer 1, for example block **1104**, will be processed last to allow for latency in the processing pipeline. Thus, in regard to code **1100**, the pipeline latency can be up to five without requiring the introduction of stall cycles which would impact throughput. The decoder scheduling parameters that facilitate the decoder functionality for the out of order PS processing and out of order R selection (referred to herein as “schedule 2”) are listed in FIG. 31 to FIG. 44. One difference between schedule 1 and schedule 2 processing is that schedule 2 provides out-of-order block processing. Both schedules process the layers in the same order, i.e., use the same S matrix.

FIG. 23 and FIG. 37 show the circulant index matrices for schedule 1 and schedule 2 respectively. The indices of the circulants processed in layer 2 of FIG. 37 are: [11 16 17 18 20 12 13 14 15 19]. The indices of the circulants processed in layer 2 of FIG. 23, are: [11 12 13 14 15 16 17 18 19 20]. In FIG. 26, the 2nd row of the DL matrix gives the dependent layer information: [8 1 1 1 1 8 8 6 1 3]. Since the circulants with circulant indices [12 13 14 15 19] in layer 2 are dependent on layer 1, these circulants in layer 2 will be processed after processing the circulants with circulant indices [11 16 17 18 20]. The resulting 2nd row DL matrix of FIG. 40 is [8 8 8 6 3 1 1 1 1 1]. Similarly, out-of-order processing is employed on each layer as is shown in FIG. 37. The matrices DCI, DB, DL, BC, SM, DSM, and UCVF are obtained by doing block reordering of their counterpart matrices of schedule 1. The block reordering information is completely specified in the CI matrix of FIG. 37. Based on the pipeline requirements of a particular hardware implementation, embodiments reorder the processing of blocks in each layer, leading to out of order processing for PS processing. Embodiments perform reordering by reordering the BC, DL, DB, DCI, SM, DSM, UCVF, and DC matrices in each row according to the reordering of block numbers in the CI matrix. For example, each row in the BC matrix is reordered differently. FIG. 39 shows the BC matrix for schedule 2 which is the reordered BC matrix of FIG. 25.

For implementations in which a pipeline depth greater than five is desirable, considering again code **1100**, an embodiment can reorder the layers first as shown in FIG. 45 and apply out of order processing for R selection and PS processing.

Here the processing sequence of layers is optimized such that the possible pipeline depth is 6. One such processing sequence of layers is [3 6 5 2 7 4 1 8]. The H matrix is reordered and the resulting S and H_b matrices are shown in FIG. 46 and FIG. 47 respectively. The decoder scheduling parameters are extracted based on out-of-order processing for R selection and PS processing. The parameters are shown in FIG. 46 to FIG. 58. Because the S and H_b matrix as seen by the decoder are changed, the decoder scheduling parameters are quite different from Schedules 1 and 2. Note, however that schedule 3 is essentially schedule 2 applied to a reordered H matrix.

Embodiments obtain improved schedules by reordering based on other criterion and other matrices as well. For example, examination of the DL matrix of FIG. 40 for schedule 2, reveals that layer 3 needs to access FS from layers [7 1 8 7 4 2 2 2 2] to generate the R new messages. The layer 7 is accessed at different processing times-however the same value is read. Embodiments can reorder the processing such that the 3rd row in the DL matrix is [7 7 1 8 4 2 2 2 2]. Since the two accesses are in consecutive processing time slots, there is only physical read access to the FS memory. This helps minimize the memory power. Similar reordering can be done on the remaining rows of DL matrix. To satisfy both the pipeline requirements and memory access requirements, the reordering of the DL matrix is done such that the DL entries that have the same value are grouped together and the entries that show dependence of the current layer on the previous layer are listed last in the processing schedule.

As an illustration of above scheduling schemes, consider the following scenarios:

SCHEDULE 1: No reordering of layers is done. Out-of-order processing for R new message generation is possible with these parameters. No out-of-order block processing is performed in PS processing.

SCHEDULE 2: No reordering of layers is done. Out-of-order processing for R new message generation is possible with these parameters. Out-of-order block processing is performed in PS processing.

SCHEDULE 3: Reordering of layers is done. Out-of-order processing for R new message generation is possible with these parameters. Out-of-order block processing is performed in PS processing.

The above scheduling parameters in all the above 3 processing schedules are applicable to a variety of decoder structures, including, for example, the decoders **1200**, **1300**, **1400** of FIGS. 12-14. A difference between these decoders is that R new messages are generated in order for decoders **1300**, **1400**, thus the decoders **1300**, **1400** have no need for the parameters DL, DB, and DCI. All the above schedules decode the 802.16e rate 2/3A code as specified in IEEE 802.16e standard—however, with different pipeline characteristics in hardware and thus different hardware efficiencies in terms of throughput. With schedule 1, the number of pipeline stages in a decoder without any stall cycles is zero. With schedule 2, the number of pipeline stages in a decoder without any stall cycles is 5. With schedule 3, the number of pipeline stages in a decoder without any stall cycles is 6.

For cases in which a pipeline depth greater than six is desirable, considering again code **1100**, an embodiment can process the blocks of layer 3 and higher layers that are independent of layers one and two. When the result from layer one is available, an embodiment can process the blocks in layers two and three that are dependent on layer one. When layer two results are also available, an embodiment can complete processing of layer three blocks dependent on layer 2. Thus embodiments perform out-of-order processing at the block

21

level and process the independent blocks. Because embodiments partially process multiple layers partial state memory should be sized to accommodate the number of layers processed.

FIG. 12 shows an LDPC decoder that uses out-of-order processing for decoding irregular LDPC codes in accordance with various embodiments. Embodiments of the decoder 1200 apply vector equations (21)-(24) which are similar to equations (9)-(12). Cyclic shifter 1214 operates as described above in regard to cyclic shifter 504 of decoder 500. Decoder 1200 differs from decoder 500 in a number of respects to enable out-of-order block processing however. The final state storage registers 230 of CNU 200 used in the CNU array 502 of decoder 500 have been moved outside of CNU array 1202 in decoder 1200 to facilitate out-of-order block processing. Thus, final state storage array 1204 provides new final state data 1218 to R new select unit 1213 and old final state data 1220 to R old select unit 1212. Similarly, Q sign memory 1226 provides stored Q sign bits 1228 to the R new select unit 1213 and the R old select unit 1212 for R message generation. Q memory 1224 is randomly accessible to provide the appropriate Q old message 1208 for generation of a new P message 1222 during out-of-order processing.

It is not possible to achieve cyclic shifts specified by $s(l, n)$, $(=0, 1, \dots, z-1)$ on a vector of length z with a cyclic shifter of size $M \times M$ if M is not a integer multiple of z . So, to accommodate the different shifts needed for WiMax LDPC codes, embodiments use a Benes network, which is of complexity $2 \log_2(M) - 1$ stages of M 2-in-1 multiplexers. In some

22

embodiments, a memory can be used to store control inputs needed for different shifts if supporting one expansion factor. The memory for providing control signals to the network is equal to

$$\frac{M}{2}(2\log_2(M) - 1)$$

bits or every shift value that needs to be supported. This results in a large memory requirement to support all the WiMax codes. To avoid the control memory requirement, embodiments employ a cyclic shifter constructed as a Master-slave Benes network to accommodate 114 different parity check matrices in run time for IEEE 802.16e. This approach eliminates the control memory requirements by generating the control signals for the slave data router with the help of a self routing master network. Note that the control memory savings are specific to an IEEE 802.16e decoder.

The following set of equations provide more details as to how equations (21)-(24) are processed in the decoder 1200. of FIG. 12.

The TDMP can be described with the following equations:

$$\forall n = 1, 2, \dots, N_b \text{ BEGIN} \quad (29)$$

$$Qs(n) = \vec{I}_n [\text{One time Initialization of } Qs \text{ memory with the channel } LLR \text{ values}]$$

END

When the decoder **1200** processing starts for a received code word, the Qs memory **1224** is initialized with the channel LLR values as in (29). The processing is generally done from layer 1 to layer M_b , and the variable/keeps track of which layer is being processed. However, to improve decoder **1200** efficiency, the layers of the H matrix are processed in a different order. The H matrix is reordered and all the decoder scheduling parameters are generated as explained in the previous sections for scheduling parameter generation. Note that this decoder **1200** structure supports out-of-order processing for R new messages, out-of-order processing for PS processing, and layer reordering.

The variable n keeps track of the number of circulants that are processed in each layer. If there is no out-of-order block processing of circulants (for PS processing), then $bn = \text{BN}(l, n) = n$; (i.e. in the nth clock of processing layer l, circulant with block number n). If there is out-of-order block processing of circulants (for PS processing), then $bn = \text{BN}(l, n)$; (i.e. in the nth clock of processing layer l, circulant with block number indexed by $\text{BN}(l, n)$ is processed). The equation (30a) loads the dc value of the layer that is being processed. The equations in (30b) initialize the partial state registers $M1_{PS}$, $M2_{PS}$, CS_{PS} . The set of equations in (31) load the parameters for each circulant that need to be processed. Generally, these scheduling parameters are generated using a computer (e.g., a PC or workstation), or an embedded processor coexisting with the decoder on the same or a different integrated circuit. The computer or embedded processor executes a software embodiment of the parameter extraction algorithm and the required decoding schedule to produce the scheduling parameters. The generated schedule is loaded into decoder memory, for example Read Only Memory ("ROM") or Random Access Memory ("RAM"). All of the scheduling parameters in matrices that are indexed by (l,n) are converted into vectors indexed by $((l-1) \cdot \text{DC}(l) + n)$ after removing any invalid entries in each row of the matrix and are stored in decoder memory. However, for clarity, scheduling parameters are shown as accessed using two indices/and n.

The equation (32) represents a simple selection of a required shift coefficient based on the variable $ucvf$. All the other equations (33-47) are vector operations. The equation (35) represents the P update. The equation (36) represents the shift operation performed on the P message. The equation (38) represents the Q update. The equation (40) represents the correction operation on Q message. The set of equations (42-44) represent the check node partial state processing of finding $M1_{PS}, M2_{PS}, \text{Min_id}_{PS}, CS_{PS}$. The CS_{PS} represents the cumulative XOR of sign messages of the Q messages processed so far in each row for all the rows in each layer. The CS_{FS} represents the cumulative XOR of sign messages of the all the Q messages in each row for all the rows in each layer. The equations (33) and (37) represent the R new message processing and R old message processing respectively.

The decoder **1200** comprises internal memories to store the internal results or processing. The Q memory **1224** may be double buffered, thus enabling reception of an incoming code word while the decoder **1200** is processing another code word. Equations (29), (34) and (39) represent the read and write operations on Q memory **1224**. The FS memory **1204** stores the FS message for all the layers. Equation (47) represents the write operation to FS memory **1204** (note that there is only one write operation per clock cycle). In equation (37), $FS(l)$ represents the read operation from FS memory **1204** to access FS old message **1220** (FS message of the layer of the previous iteration). Note that there is only one read access for each layer as the read address is l inside each sub-iteration loop/layer processing loop.

The decoder contains a separate hard decision memory HD memory which is not shown in **1200**. The hard decision bits are the sign bits of P message. The HD memory may also be double buffered, thus enabling processing of the incoming code while sending the decoder decisions to the output interface. The HD memory may have more than two buffers, thus enabling statistical processing of the incoming code words to provide a constant average throughput. This enables the decoder to buffer the hard decisions of the frames that were

25

previously decoded. Since the output interface expects the frames in the same order as they are fed in at the input interface, the HD memory buffers the frames that were processed out-of-order and sends them in-order.

The Q memory **1224** may have more than two buffers, thus enabling statistical processing of the incoming code words to provide a constant average throughput. The incoming code words may differ in the number of errors contained, so the decoder may need a different number of iterations for each frame based on its quality. Allocation of the maximum number of LDPC decoder iterations for each frame can be chosen based on the number of failing LDPC check node constraints in the received frame.

When the LDPC decoder is used as part of an iterative detector in combination with an Inter-Symbol Interference (“ISI”) detector, the Q memory can be used to buffer the Channel LLRs from the ISI detector, Extrinsic messages from the LDPC decoder, and to serve as internal storage for the LDPC decoder’s Q messages. Statistical buffering can be applied in this case also. In addition to the Q memory and HD memory, the input memory to the ISI detector is also statistically buffered. The input memory to the ISI detector stores the received samples from the previous block in the receiver chain, for example, a Finite Impulse Response filter. Since both the ISI detector and the LDPC decoder work in an outer loop called global iteration, the statistical buffering of Q memory and input memory to the ISI detector would be on the same frames that are not yet decoded or not yet fully decoded (i.e., some of the frames are processed already, however they have not yet converged so further iterations are necessary). The statistical buffering of HD memory is to enable keeping the frames that are already decoded.

In decoder **1200**, out-of-order processing for R new message generation is employed. In equation (33) FS(dl) represents the read operation from FS memory to access FS new message **1218** (FS message of the dependent layer of the currently processed circulant). Note that there can be as many as dc read accesses for each layer as the read address is dl inside each sub-iteration and each layer can have as many as min(dc, M_b) dependent layers.

The Qsign memory **1226** stores the signs of all the Q messages of all the circulants in the H matrix. The equation (41) represents the write operation to Qsign memory and the equation (33) represents the read operation from Qsign memory while generating the R new messages.

The following set of equations provides more details as to how equations (21)-(24) are processed in the decoder **1300** of FIG. **13**. The TDMP can be described with the following equations:

$$\begin{aligned}
 &\forall n = 1, 2, \dots, N_b \text{ BEGIN} & (48) \\
 &P(n) = \vec{L}_n [\text{One time Initialization} \\

 \end{aligned}$$

different order. The H matrix is reordered and all the decoder scheduling parameters are generated as explained in the previous sections for scheduling parameter generation. Since out-of-order processing for R new messages is not employed in the decoder **1300**, there is no need for scheduling parameters DCI, DB, or DL. Note that the decoder **1300** supports out-of-order processing for PS processing and layer reordering.

The variable n keeps track of the number of circulants that are processed in each layer. If there is no out-of-order block processing of circulants (for PS processing), then $bn=BN(l, n)=n$; (i.e., in the nth clock of processing layer l, circulant with block number n). If there is out-of-order block processing of circulants (for PS processing), then $bn=BN(l, n)$; (i.e., in the nth clock of processing layer l, circulant with block number indexed by $BN(l, n)$ is processed). The equation (49a) loads the dc value of the layer that is being processed. The equations in (49b) initialize the partial state registers $M1_{PS}$, $M2_{PS}$, CS_{PS} . The set of equations in (50) load the parameters for each circulant that needs to be processed. Generally, these scheduling parameters are generated using a computer (e.g., a PC or workstation), or an embedded processor coexisting with the decoder on the same or a different integrated circuit. The computer or embedded processor executes a software embodiment of the parameter extraction algorithm and the required decoding schedule to produce the scheduling parameters. The generated schedule is loaded into decoder memory, for example Read Only Memory ("ROM") or Random Access Memory ("RAM"). All of the scheduling parameters in matrices that are indexed by (l,n) are converted into vectors indexed by $((l-1) \cdot DC(l) + n)$ after removing any invalid entries in each row of the matrix and are stored in decoder memory. However, for clarity, scheduling parameters are shown as accessed using two indices/and n.

The equation (51) represents a simple selection of a required shift coefficient based on the variable ucvf. All the other equations (52-70) are vector operations. The equation (69) represents the P update. The equation (53) represents the shift operation performed on the P message. The equation (56) represents the Q update. The equation (58) represents the correction operation on the Q message. The set of equations (60-63) represent the check node partial state processing of finding $M1_{PS}$, $M2_{PS}$, Min_id_{PS} , CS_{PS} . The CS_{PS} represents the cumulative XOR of signs of the Q messages processed so far in each row for all the rows in each layer. The CS_{PS} represents the cumulative XOR of signs of the all the Q messages in each row for all the rows in each layer. The equations (54) and (67) represent the R new message processing and R old message processing.

The decoder **1300** comprises internal memories to store the internal results of processing. The P memory **1330** may be double buffered, thus enabling reception of an incoming code word while the decoder **1300** is processing another code word. Equations (48), (52) and (70) represent the read and write operations on P memory **1330**. Note that in a hardware implementation all the vector processing in the set of equations from (66)-(70) are done on the previously processed layer while the set of equations (52)-(65) are done on the currently processed layer l. Note further that the read operation of equation (52) may create a conflict if the write operation of equation (70) to the same block column in the previously processed layer is not complete. Such read before write conflicts may be handled through insertion of stall cycles. However, embodiments employ a better solution by applying out-of-order processing on PS processing (as in schedule 2 which provides 5 pipeline stages without any stall cycles),

and in layer reordering and out-of-order processing on PS processing (as in schedule 3 which provides 6 pipeline stages without any stall cycles).

The FS memory **1304** stores the FS message for all the layers ("m" in FIGS. 13 and 14 represents the number of layers M_b). Equation (65) represents the write operation to FS memory. Note that there is only one write operation per clock cycle. In equation (54), $FS(l)$ represents the read operation from FS memory **1304** to access FS old message (FS message of the layer of the previous iteration). Note that there is only one read access for each layer as the read address is/inside each sub-iteration loop/layer processing loop.

The Q FIFO **1324** stores the Q messages **1306** that are sent as inputs to the CNU **1302** and stores them till the CNU processing is complete. Equation (57) represents the write to the Q FIFO **1324** and equation (68) represents the read from Q FIFO **1324**.

In decoder **1300**, out-of-order processing for R new message **1326** generation is not employed. So there are no read accesses for FS memory **1304** in this decoder configuration for the R new message **1326** generation. The R new messages **1326** are generated in-order as is done in the layered decoder **500** of FIG. 5.

The Q sign memory **1310** stores the signs **1308** of all the Q messages of all the circulants in the H matrix. The equation (59) represents the write operation to Q sign memory and the equation (67) represents the read operation from Q sign memory while generating the R new messages **1326**. In decoder **1300**, equation (55) is not needed because we are not storing the R old messages **1316**.

The set of equations (48)-(65) and the set of equations below provide more details as to how equations (21)-(24) are processed in the decoder **1400** of FIG. 14. However, the second block column loop is different and this difference is described by equations (71)-(76) instead of equations in (66)-(70). The Q FIFO is not needed in decoder **1400**. Equation (57) in the first block loop is not needed for decoder **1400**. However, in decoder **1400**, equation (55) is needed because the R old messages are stored and these messages are read in equation (73). In another embodiment of decoder **1400**, the memory for R old messages is omitted by generating delayed R old messages from FS memory **1404** using the value-reuse property (i.e., equation (54) is repeated to generate the delayed R old messages). Thus, embodiments avoiding the FIFO requirement for delayed R old messages have three R message generation units: R new, R old and delayed R old (some times referred to as R prev).

$$\forall n = 1, 2, \dots, dc, [\text{Another Block loop}] \text{BEGIN} \quad (71)$$

$$ci = CI(l, bn);$$

$$bn = BN(l, n);$$

$$R_{new} = R_Select(FS_temp, bn, Qsign(ci)); \quad (72)$$

$$R_{prev} = R_{old_delayed}(n); \quad (73)$$

$$P_{old} = P(bc); \quad (74)$$

$$P_{new} = P_{old} + R_{new} - R_{prev}; \quad (75)$$

$$P(bc) = P_{new}; \quad (76)$$

END

When constructing the LDPC code matrix itself, layer ordering and block ordering requirements can be taken into account. Independence between adjacent layers can be maxi-

mized so that while processing the current layer, the next layer has few dependencies on the current layer.

Some embodiments use scheduled layered approximation as described herein below. In the case of regular LDPC codes with no null matrices, it is not possible to gain any benefit from out-of-order block processing in the block serial decoder **500** of FIG. **5**. To enable pipelining without stall cycles, the decoder allows some of the blocks in the currently processed layer to take the updated P message from the layer that is already processed. For instance, consider (5,25) regular LDPC code. Assume that a pipeline depth of 4 is needed to meet the required frequency target for a given throughput and hardware area. Processing each layer takes 25+4 clock cycles if 4 stall cycles are added for 4 pipeline stages. Assume each layer is processed in a layer-time slot that takes 25 clock cycles. The presently processed layer takes the updated P message from the layer that was processed in the previous layer-time slot. It is possible to approximate the layered decoding such that the presently processed layer takes the updated P message from the layer that was processed two layer-time slots previously. However, this layered approximation introduces significant bit error rate performance loss. Embodiments solve this problem by enforcing layered approximation on the circulant level rather than on at the layer level. Since a pipeline depth of 4 is needed, the decoder first processes 4 out of 25 blocks in each layer with the P message update from the layer that was processed two layer-time slots previously. The decoder then processes the remaining 21 blocks out of 25 blocks in each layer with the P message update from the layer that was processed one layer-time slot previously as in the usual layered decoding. To avoid any error floor issues due to the preferential treatment to some of the circulants in H matrix, the decoder changes the set of circulants which would receive the regular layered update and the set which would receive the approximate layered update. Thus, the decoder selects a new set of, for example, 4 circulants that will undergo approximate layered decoding each iteration. The selected circulants can be changed each iteration. In this way after about 6 iterations all of the 25 blocks receive the layered update.

While illustrative embodiments of this invention have been shown and described, modifications thereof can be made by one skilled in the art without departing from the spirit or teaching of this invention. The embodiments described herein are illustrative and are not limiting. Many variations and modifications of the methods and apparatus are possible and are within the scope of the invention. Accordingly, the scope of protection is not limited to the embodiments described herein, but is only limited by the claims which follow, the scope of which shall include all equivalents of the subject matter of the claims.

What is claimed is:

1. A low density parity check code decoder, comprising: a control unit that controls decoder processing, the control unit configured to:
 cause the decoder to process blocks of a low density parity check ("LDPC") matrix out of order; and
 schedule computation of R messages for a first non-zero block and computation of P messages and Q messages for a second non-zero block such that R messages for the first non-zero block are generated while processing the second non-zero block based on a determination of need for the R messages for the computation of P and Q messages for the second non-zero block;
 wherein the first non-zero block and the second non-zero block are in a same column of the matrix.

2. The decoder of claim **1**, wherein the control unit causes the decoder to process layers of the LDPC matrix out of order.

3. The decoder of claim **1**, further comprising an array of check node units that perform partial state processing on blocks of the LDPC matrix.

4. The decoder of claim **3**, wherein the check node units perform partial state processing on out of order blocks of the LDPC matrix.

5. The decoder of claim **1**, wherein the control unit is configured to cause the decoder to update the P message based on a determination of a final state for each block row.

6. The decoder of claim **1**, further comprising an R select unit that provides an R message based on the values stored in a final state storage array, wherein the R select unit produces the R message of a dependent layer block based on a determination that a non-zero block being processed in a current layer of a present column of the matrix.

7. The decoder of claim **1**, further comprising an R select unit that provides an R message based on the values stored in a final state storage array, wherein the R select unit produces the R message for a layer of the matrix currently being processed.

8. The decoder of claim **1**, wherein the control unit schedules no processing of zero blocks of the LDPC matrix.

9. The decoder of claim **1**, wherein the control unit is configured to cause the decoder to scheduling R new message computation of a block independent of partial state processing of the block row to which the block belongs.

10. The decoder of claim **1**, wherein the control unit is configured to cause the decoder to process each block of the matrix in processing substeps comprising:

an R new update substep that provides an R new message, wherein the R new message is produced for a block of a different layer of the matrix from a layer containing a block currently being processed;

an R old update substep that: selects an R old message, wherein the R old message is produced for a layer of the matrix currently being processed;

a P message substep that generates updated P messages;
 a Q message substep that computes variable node messages (Q messages); and

a partial state substep that updates partial state of a block row based on Q messages computed for the block (CNU Partial state processing).

11. The decoder of claim **10**, further comprising a selector coupled to the Q message storage array, the selector selects one of a Q message and a channel log-likelihood ratio ("LLR") for storage in the Q message storage array, wherein the selector selects an LLR to initialize the decoder.

12. The decoder of claim **1**, further comprising a P sum adder array that sums a Q message provided by a Q message storage array and an R new message provided by an R new selector unit to produce an updated P message.

13. The decoder of claim **1**, further comprising a cyclic shifter that shifts an updated P message.

14. The decoder of claim **1**, further comprising a Q subtractor array that subtracts an R old message from a shifted updated P message to produce an updated Q message.

15. The decoder of claim **1**, wherein the controller comprises a storage array that stores sequence information that determines the processing order of at least one of matrix blocks, R new messages, and matrix layers.

16. The decoder of claim **15**, wherein the sequence information is selected based on at least the LDPC matrix to be decoded.

31

17. The decoder of claim 1, wherein a number of processing elements in the decoder is based on the size of a circulant processed, and wherein the circulant is processed in block serial fashion.

18. A method for decoding a low density parity check code, comprising:

processing blocks of a low density parity check (“LDPC”) matrix out of order; and

scheduling computation of R messages for a first non-zero block and computation of P messages and Q messages for a second non-zero block such that R messages for the first non-zero block are generated while processing the second non-zero block based on a determination of need for the R messages for the computation of P and Q messages for the second non-zero block;

wherein the first non-zero block and the second non-zero block are in a same column of the matrix.

19. The method of claim 18, further comprising processing layers of the LDPC matrix out of order.

20. The method of claim 18, further comprising scheduling R new message computation of a block independent of partial state processing of the block row to which the block belongs.

21. The method of claim 18, further comprising providing an R message based on the values stored in a final state storage array, wherein an R message of a dependent layer block is produced based on a determination that a non-zero block being processed in a current layer of a present column of the matrix.

22. The method of claim 18, further comprising selecting an R message based on the values stored in a final state storage array, wherein the R message is produced for a layer of the matrix currently being processed.

23. The method of claim 18, further comprising processing each block of the matrix in processing substeps comprising:

32

an R new update substep that provides an R new message, wherein the R new message is produced for a block of a different layer of the matrix from a layer containing a block currently being processed;

an R old update substep that: selects an R old message, wherein the R old message is produced for a layer of the matrix currently being processed;

a P message substep that generates updated P messages; a Q message substep that computes variable node messages (Q messages); and

a partial state substep that updates partial state of a block row based on Q messages computed for the block (CNU Partial state processing).

24. The method of claim 18, further comprising scaling a Q message provided to CNU array to reduce the magnitude of the Q message.

25. The method of claim 18, further comprising selecting one of a Q message and a channel log-likelihood ratio (“LLR”) to generate a P message, the LLR is selected to initialize decoding.

26. The method of claim 18, further comprising update the P message based on a determination of a final state for each block row.

27. The method of claim 18, further comprising cyclically shifting an updated P message.

28. The method of claim 19, further comprising subtracting an R old message from a shifted updated P message to produce an updated Q message.

29. The method of claim 18, further comprising determining the processing order of at least one of matrix blocks, R new messages, and matrix layers based on sequence information based at least in part on the LDPC matrix to be decoded.

30. The method of claim 18, further comprising processing a circulant in sub-block serial fashion.
