

Measurement of the top quark mass with the dynamical likelihood method using lepton plus jets events with b -tags in pp collisions at $s\sqrt{=}1.96$ TeV

CDF Collaboration

CAMPANELLI, Mario (Collab.), *et al.*

Abstract

This paper describes a measurement of the top quark mass, M_{top} , with the dynamical likelihood method (DLM) using the CDF II detector at the Fermilab Tevatron. The Tevatron produces top/antitop ($t\bar{t}$) pairs in pp collisions at a center-of-mass energy of 1.96 TeV. The data sample used in this analysis was accumulated from March 2002 through August 2004, which corresponds to an integrated luminosity of 318 pb^{-1} . We use the $t\bar{t}$ candidates in the "lepton+jets" decay channel, requiring at least one jet identified as a b quark by finding a displaced secondary vertex. The DLM defines a likelihood for each event based on the differential cross section as a function of M_{top} per unit phase space volume of the final partons, multiplied by the transfer functions from jet to parton energies. The method takes into account all possible jet combinations in an event, and the likelihood is multiplied event by event to derive the top quark mass by the maximum likelihood method. Using 63 $t\bar{t}$ candidates observed in the data, with 9.2 events expected from background, we measure the top quark mass to be [...]

We report a search for the flavor-changing neutral-current decay of the top quark $t \rightarrow Zq$ ($q = u, c$) in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV using a data sample corresponding to an integrated luminosity of 1.9 fb^{-1} collected by the CDF II detector. This decay is strongly suppressed in the standard model and an observation of a signal at the Fermilab Tevatron would be an indication of physics beyond the standard model. Using $Z + \geq 4$ jet final state candidate events, with and without an identified bottom quark jet, we obtain an upper limit of $\mathcal{B}(t \rightarrow Zq) < 3.7\%$ at 95% C.L.

Flavor-changing neutral-current (FCNC) interactions, which mediate transitions from one type of quark to another with the same electric charge, are suppressed in the standard model of particle physics (SM). FCNC processes are therefore sensitive indicators of physics beyond the SM (BSM). Presently there are only loose experimental bounds on FCNC decays of the t (top) quark [1], the heaviest known quark. While the SM branching fraction for $t \rightarrow Zq$ ($q = u, c$) is predicted to be $\mathcal{O}(10^{-14})$ [2], BSM models such as supersymmetry and quark compositeness allow branching fractions as high as $\mathcal{O}(10^{-4})$ [2,3]. An observation of the top FCNC decay $t \rightarrow Zq$ with current samples would be a strong indication of BSM physics.

In Run I, a CDF search for the $t \rightarrow Zq$ decay yielded the branching fraction upper limit $\mathcal{B}(t \rightarrow Zq) < 33\%$ (95% C.L.) [4]. The current best 95% C.L. upper limit on $\mathcal{B}(t \rightarrow Zq)$, 13.7%, was set by the L3 experiment [5] from the nonobservation of FCNC single t quark production. These analyses assumed a t quark mass of $m_t = 175 \text{ GeV}/c^2$. In this Letter we also assume $m_t = 175 \text{ GeV}/c^2$ and evaluate the small effect of different m_t on the result.

We present the first Tevatron Run II search for the top FCNC decay $t \rightarrow Zq$ in $t\bar{t}$ pairs. The data sample analyzed for this Letter corresponds to an integrated luminosity of 1.9 fb^{-1} of $p\bar{p}$ collisions at $\sqrt{s} = 1.96 \text{ TeV}$, collected by the CDF II detector from March 2002 to May 2007. Our primary signal signature consists of the FCNC decay $t \rightarrow Zq$ ($q = u, c$) together with the dominant SM decay $\bar{t} \rightarrow W^- \bar{b}$ (charge conjugate modes are implied). We search for the Z boson via its decays $Z \rightarrow e^+e^-$ and $Z \rightarrow \mu^+\mu^-$ and for the decay of the W boson into a quark-antiquark pair. Two leptons and at least four jets of hadrons, coming from the four quarks from secondary decays, can be observed in the detector. We also allow for events in which both t quarks undergo FCNC decays.

The components of the CDF II detector relevant to this analysis are briefly described here; a more complete description can be found elsewhere [6]. The transverse momenta p_T and pseudorapidities η [7] of charged particles are measured by a silicon strip detector [8] and a 96-layer drift chamber (COT) [9] inside a 1.4 T solenoidal magnetic field. The silicon detector and the COT provide good combined reconstruction efficiency for $|\eta| < 1.2$. Electromagnetic (EM) and hadronic calorimeters measure energies of charged and neutral particles in the central ($|\eta| < 1.1$) and end-plug ($1.1 < |\eta| < 3.6$) regions. Drift chambers and scintillation counters located on the rear of the calorimeters and behind an additional steel absorber detect muons with $|\eta| < 1.0$. A three-level trigger selects events that contain electrons (muons) with $E_T > 18 \text{ GeV}$ ($p_T > 18 \text{ GeV}/c$).

We consider several SM background processes that also result in final states with a reconstructed Z boson and four or more jets. The dominant background process is the production of Z bosons with associated jets ($Z + \text{jets}$).

Smaller contributions come from SM $t\bar{t}$ production and the production of pairs of gauge bosons (dibosons), WZ and ZZ . The contributions from WW diboson production and from W bosons produced in association with jets are negligible.

We use the PYTHIA v6.216 Monte Carlo (MC) generator [10] to simulate the FCNC signal in $t\bar{t}$ events and all sources of SM background, except $Z + \text{jets}$ production, whose kinematic distributions we simulate with the ALPGEN MC generator [11], v2.10' interfaced to PYTHIA v6.325. Acceptance, efficiency, and kinematic distributions of signal and background are determined from the above MC simulations. We generated a full spectrum of FCNC signal MC simulations including $t\bar{t} \rightarrow ZqWb$ with $q = c$, $t\bar{t} \rightarrow ZqWb$ with $q = u$ (the probability to b -tag an FCNC signal event is reduced from 50% to 45%) where we apply the SecVtx algorithm [6] for the b -tagging, and where both top quarks decay via the FCNC mode. The amount of $t\bar{t} \rightarrow ZqZq$ relative to $t\bar{t} \rightarrow WbZq$ is adjusted according to the branching fraction $\mathcal{B}(t \rightarrow Zq)$ during the limit calculation.

The analysis proceeds in three steps. Our base selection requires a Z boson and four or more jets. An optimized event selection separates the FCNC signal from the SM backgrounds based on kinematic properties of the event. All events that pass the optimized selection are further divided into two signal regions based on whether any of the four leading jets has an identified b jet (“ b -tagged region”) or not (“non- b -tagged region”); those events that pass the base selection but not the optimized selection are placed in a “control” region. While only 12% of FCNC signal acceptance falls in the control region, two-thirds of the SM backgrounds are located there. We finally fit the data to one-dimensional probability density histograms (“templates”) of one of the kinematic distributions (mass χ^2 , see below) to derive a limit on $\mathcal{B}(t \rightarrow Zq)$. This is illustrated in Fig. 1. To reduce systematic uncertainties, the measurement is normalized to the measured event yield in SM $t\bar{t}$ production.

Our base selection chooses events with two oppositely-charged leptons of the same flavor (e or μ) and four or more jets. One lepton is required to be a central electron or muon; the other can be a forward electron or a track, as described below. The leptons must be compatible with originating from a Z boson in the mass window from $76 \text{ GeV}/c^2$ to $106 \text{ GeV}/c^2$ ($>3\sigma$ in units of CDF’s Z mass resolution).

We use the standard CDF requirements for isolated electrons and muons [12]. In addition to identified electrons and muons, we double the acceptance for leptonic Z decays by allowing one of the two lepton candidates to satisfy weaker selection criteria, requiring only an isolated track which passes COT and silicon detector track quality cuts. For tracks used as electrons, if an EM calorimeter tower is associated with the track and the energy of the EM

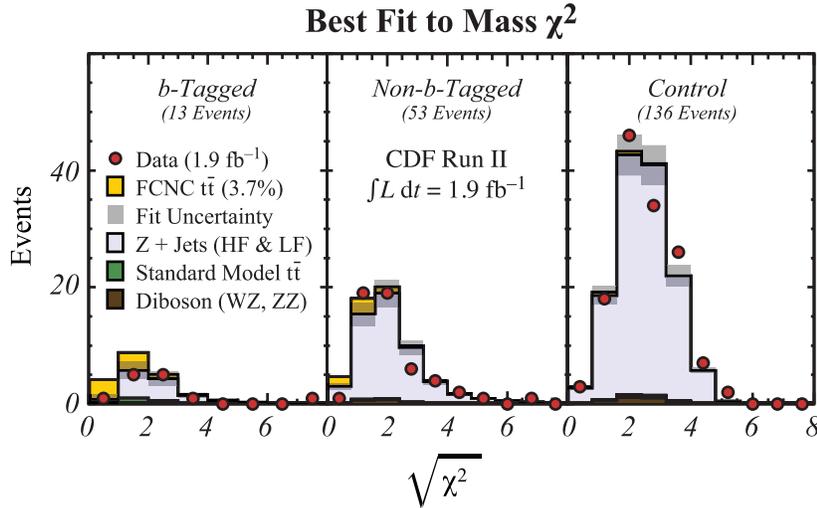

FIG. 1 (color). Mass χ^2 distribution for b -tagged and non- b -tagged signal regions and the control region. The data points as a function of $\sqrt{\chi^2}$ are compared to the SM background prediction and the expected FCNC yield at the observed 95% C.L. upper limit on the branching fraction $\mathcal{B}(t \rightarrow Zq) < 3.7\%$. The data are consistent with the background prediction.

tower is greater than the track momentum, the EM tower energy is used instead of the track momentum.

Jets are identified by energy deposited in the calorimeters within a cone of $\Delta R < 0.4$. To improve the parton energy estimate, jets are corrected for instrumental effects [13]. We select events with at least four jets with corrected $E_T > 15$ GeV and $|\eta| < 2.4$.

We separate the FCNC signal from the MC background with the help of further selection criteria in addition to the above base selection that will form the optimized selection, a mass χ^2 , the transverse mass of the system, and the E_T of the four leading (highest E_T) jets.

The decay $t\bar{t} \rightarrow WbZq \rightarrow q\bar{q}'b\ell\ell q''$ contains no high-energy neutrinos; therefore, we can fully reconstruct the event kinematics. The four jets in signal events result from the b quark and the decay products of the W in the $t \rightarrow Wb$ decay, and the c or u quark from the $t \rightarrow Zq$ decay. We form all permutations of the four leading jets in the events to compare the reconstructed masses (m_{rec}) of the W , top quark decaying to Wb , and top quark decaying to Zq . We define a mass χ^2 as

$$\chi^2 = \left(\frac{m_{W,\text{rec}} - m_W}{\sigma_W} \right)^2 + \left(\frac{m_{t \rightarrow Wb,\text{rec}} - m_t}{\sigma_{t \rightarrow Wb}} \right)^2 + \left(\frac{m_{t \rightarrow Zq,\text{rec}} - m_t}{\sigma_{t \rightarrow Zq}} \right)^2, \quad (1)$$

and select the permutation with the smallest χ^2 . We scale the measured four-momenta of the W and Z boson daughter particles such that the boson masses are fixed to the world average values [14] and use the scaled four-momenta to calculate the two top quark masses. The widths used are given by the standard deviations of the reconstructed masses measured in the MC simulation of FCNC events. Using the correct pairing of jets to partons, we extract $\sigma_W = 15$ GeV/ c^2 , $\sigma_{t \rightarrow Wb} = 24$ GeV/ c^2 , and $\sigma_{t \rightarrow Zq} = 21$ GeV/ c^2 . We expect FCNC signal events to populate the low χ^2 region and background events to result in higher

χ^2 ; see Fig. 1. We have verified that the components of Eq. (1) describe the data well in events with a Z boson and three jets.

Since the FCNC signal events originate from $t\bar{t}$ decays, they contain more central Z bosons and jets than background events. To exploit this, we use the transverse mass of the Z and the four leading jets, defined as $m_T = \sqrt{(\sum E_T)^2 - (\sum \vec{p}_T)^2}$, as a selection criterion. We also apply a tiered cut on the E_T of the four leading jets, as FCNC signal events contain jets with higher transverse momenta than SM background events.

We optimized these additional selection criteria for the best expected limit on $\mathcal{B}(t \rightarrow Zq)$ in the absence of a signal, using the MC simulation and a signal-depleted control region in the data ($\sqrt{\chi^2} > 3$). The optimization was performed in the blind phase of a counting experiment analysis using the first 1.1 fb $^{-1}$ of integrated luminosity [15]. We leave the optimized selection unchanged for the full 1.9 fb $^{-1}$ result; it requires transverse mass $m_T \geq 200$ GeV/ c^2 , leading jet $E_T \geq 40$ GeV, second jet $E_T \geq 30$ GeV, third jet $E_T \geq 20$ GeV, and fourth jet $E_T \geq 15$ GeV. After optimization, 88% of the FCNC signal events from the base selection fall into the two signal regions, compared to 33% of the background events. The inclusive signal acceptances for the decay $t\bar{t} \rightarrow WbZc$ ($t\bar{t} \rightarrow ZcZc$) are 0.43% (0.58%) for the b -tagged selection, 0.34% (0.86%) for the non- b -tagged selection, and 0.10% (0.16%) for the control region.

To determine the FCNC branching fraction, we take into account single or double FCNC decays of $t\bar{t}$ pairs and normalize to the event yield of a selection for the SM decay $t\bar{t} \rightarrow WbWb \rightarrow \ell\nu b\bar{q}q'/b$ (“lepton + jets”) requiring at least two jets to be secondary vertex b -tagged [16]. In 1.9 fb $^{-1}$ we observe 277 $t\bar{t}$ candidate events, consistent with a production cross section of $8.8 \pm 0.7(\text{stat.})$ pb assuming $\mathcal{B}(t \rightarrow Wb) = 100\%$. If $t \rightarrow Zq$ decays were present, these additional $t\bar{t}$ decays are less likely to be recon-

structed in the lepton + jets mode, resulting in a measured $t\bar{t}$ production cross section smaller than the actual cross section. We correct for this effect by modifying the measured cross section based on the limit we set on $\mathcal{B}(t \rightarrow Zq)$.

We extract a limit on the branching fraction $\mathcal{B}(t \rightarrow Zq)$ from a fit to the mass χ^2 distribution using templates constructed from the MC simulated mass χ^2 distributions of the FCNC signal and the SM backgrounds ($Z + \text{jets}$, SM $t\bar{t}$, and dibosons). The normalization of the dominant $Z + \text{jets}$ background is the most difficult to estimate from data and MC simulations; therefore, it is extracted from the fit. The SM $t\bar{t}$ background is normalized to the observed event yield in the lepton + jets decay mode; backgrounds from diboson production are normalized to their theoretical cross sections. Both contributions are fixed in the fit. The expected background from SM $t\bar{t}$ production and diboson production is 2.2 ± 0.2 (3.2 ± 0.2) events for the b -tagged (non- b -tagged) selection. The b -tagged, the non- b -tagged, and the control regions are fit simultaneously. We include systematic uncertainties due to the shapes of the signal and background templates by allowing the templates to change shape via a histogram interpolation technique (horizontal template morphing) [17]. The uncertainty due to the experimental jet energy scale (JES) is more than 3 times larger than any other uncertainty, and the data are most consistent with a shift of the JES; therefore, we only include JES-induced shape uncertainties in the fitting procedure.

We use the signal-depleted control region to constrain the background shape uncertainties without losing sensitivity to a small FCNC signal. Additionally we use the number of $Z + \text{jets}$ events observed in the control region, Z_{control} , to place a loose constraint on the number of $Z + \text{jets}$ events in the two signal regions, Z_{signal} . We constrain the ratio $\mathcal{R}_{\text{sig}} = Z_{\text{signal}}/Z_{\text{control}}$ to the value estimated by the MC simulation, $\mathcal{R}_{\text{sig}} = 0.51 \pm 0.10$ at the nominal JES. The uncertainty is conservatively estimated by varying the energy scales in the ALPGEN MC generator. We adjust \mathcal{R}_{sig} as a function of the JES shift σ_{JES} , keeping the relative uncertainty of 20%. The absolute number of $Z + \text{jets}$ background events remains unconstrained. To reflect the constraint on \mathcal{R}_{sig} in the template fit,

TABLE I. Results of the fit to data. From the ratio of the number of $Z + \text{jet}$ events in the signal and the control regions and the tagging fraction f_{tag} , we obtain $Z_{\text{tagged}} = 13.5$ events and $Z_{\text{nontagged}} = 53.9$ events.

Fit Parameter	Value
Branching Fraction, $\mathcal{B}(t \rightarrow Zq)$ (%)	-1.49 ± 1.52
$Z + \text{Jets}$ Events in Control Region, Z_{control}	129.0 ± 11.1
Ratio Signal/Control Region, \mathcal{R}_{sig}	0.52 ± 0.07
Tagging Fraction, f_{tag}	0.20 ± 0.06
Jet Energy Scale Shift, σ_{JES}	-0.74 ± 0.43

we parametrize the number of $Z + \text{jet}$ events passing the b -tagged and non- b -tagged signal selections, Z_{tagged} and $Z_{\text{nontagged}}$, as $Z_{\text{tagged}} = f_{\text{tag}} \mathcal{R}_{\text{sig}} Z_{\text{control}}$ and $Z_{\text{nontagged}} = (1 - f_{\text{tag}}) \mathcal{R}_{\text{sig}} Z_{\text{control}}$, where f_{tag} is the fraction of $Z + \text{jets}$ events passing the b -tagged signal selection. From the template fit to the data we measure a branching fraction $\mathcal{B}(t \rightarrow Zq) = -1.49\%$. The fit result is summarized in Table I and in Fig. 1.

We employ a Feldman-Cousins (FC) limit calculation framework that includes the handling of systematic uncertainties [18]. The FC construction is based on applying the above template fits to simulated experiments that are generated taking into account all known sources of systematic rate and shape uncertainty and their correlations (systematic uncertainties are discussed in the next paragraphs). We expect a limit of $(5.0 \pm 2.2)\%$ in the absence of signal. From the FC construction we find $\mathcal{B}(t \rightarrow Zq) < 3.7\%$ at 95% C.L.

We have studied systematic uncertainties due to shape uncertainties of the fitted templates, rate uncertainties (signal acceptance, background rate), and due to the normalization to the lepton + jets event yield. We treat the dominant source of template shape uncertainties, the experimental JES, as a free fit parameter. To account for further shape uncertainties, we measure the bias on the fitted branching fraction $\mathcal{B}(t \rightarrow Zq)$ in simulated experiments generated assuming the second largest source of shape uncertainties, the MC generator used for the $Z + \text{jets}$ background. We simulate $Z + \text{jets}$ events for which the vertex energy scale is varied by factors of two and assign the measured relative branching fraction bias at $\mathcal{B}(t \rightarrow Zq) = 3.7\%$ as a systematic uncertainty (5.6%).

The rate uncertainties, summarized in Table II, are divided into anticorrelated uncertainties, those which cause migration of events between b -tagged and non- b -tagged selections, and correlated uncertainties, those which simultaneously increase or decrease both selections. The signal acceptance systematic uncertainties are evaluated for the ratio of the FCNC signal acceptance to the acceptance for

TABLE II. Systematic uncertainties of the FCNC signal acceptance relative to the acceptance of the lepton + jets normalization mode and the background rate for the b -tagged and non- b -tagged selections. All values are percentages.

Systematic Uncertainty	Acceptance		Background	
	b	Non-b	b	Non-b
ID, Trig, and PDF	1.0	1.0	1.5	1.5
Initial/Final State Rad.	4.8	5.5
Z Helicity	3.4	3.6
Total Correlated	6.2	6.1	6.2	6.2
b -Tagging	5.6	16.1	3.2	2.5
$\mathcal{B}(t \rightarrow Zc)$ vs $\mathcal{B}(t \rightarrow Zu)$	4.5	4.5
Total Anti-Correlated	7.2	16.7	3.2	2.5

the event selection used in the lepton + jets normalization mode. Background rate uncertainties affect only the smaller SM $t\bar{t}$ and diboson backgrounds. The rate of the dominant Z + jets background in the control region is a free parameter in the fit; therefore, we do not assign systematic uncertainties for this.

Normalization to the lepton + jets event yields in the $t\bar{t}$ production cross section analysis removes nearly all uncertainties depending directly on luminosity. Many other systematic uncertainties also partially cancel. We absorb the statistical and systematic uncertainties of the $t\bar{t}$ production cross section measurement as part of the systematic uncertainty (7.8%).

In conclusion, we have searched for the top quark flavor-changing neutral-current decay $t \rightarrow Zq$ in events with a Z boson and four or more jets using CDF Run II data corresponding to 1.9 fb^{-1} of integrated luminosity. The data are consistent with the SM background prediction, and we set an upper limit on the branching fraction $\mathcal{B}(t \rightarrow Zq)$ of 3.7% at 95% C.L. at a top quark mass of $175 \text{ GeV}/c^2$. Assuming a top quark mass of $170 \text{ GeV}/c^2$, the 95% C.L. upper limit is 4.1%. Compared with the previous world's best limit of 13.7% by the L3 experiment [5] at LEP2, and the previous Tevatron upper limit of 33%, as reported by CDF Run I [4], our reported limit of 3.7% represents a substantial improvement.
