## **ABSTRACT**

Sensitivity Analysis of Flexible Pavement Response and AASHTO 2002 Design Guide  
for Properties of Unbound Layers. (May 2004)

Sanaa Masad, B.S., Jordan University of Science and Technology

Chair of Advisory Committee: Dr. Dallas N. Little

Unbound granular materials are generally used in road pavements as base and subbase layers. The granular materials provide load distribution through aggregate contacts to a level that can help the subgrade to withstand the applied loads.

Several research studies have shown that unbound pavement layers exhibit anisotropic properties. Anisotropy is caused by the preferred orientation of aggregates and compaction forces. The result is unbound pavement layers that have higher stiffness in the vertical direction than in the horizontal direction. This behavior is not accounted for in the design and analysis procedures included in the proposed AASHTO 2002 design guide.

One of the objectives of this study is to conduct a comparative analysis of flexible pavement response using different models for unbound pavement layers: linear isotropic, nonlinear isotropic, linear anisotropic and nonlinear anisotropic. Pavement response is computed using a finite element program. The computations from nonlinear isotropic and anisotropic models of unbound layers are compared to the AASHO field experimental measurements.

The second objective is to analyze the influence of using isotropic and anisotropic properties for the pavement layers on the performance of flexible pavements calculated using the AASHTO 2002 models.

Finally, a comprehensive sensitivity analysis of the proposed AASHTO 2002 performance models to the properties of the unbound pavement layers is conducted. The sensitivity analysis includes different types of base materials, base layer thicknesses, hot mix asphalt type and thickness, environmental conditions, and subgrade materials.

## **DEDICATION**

This thesis is dedicated to my parents and my brother Eyad (Dr. Masad) for providing me the support that I needed to finish this thesis.

## ACKNOWLEDGMENTS

I would like to take this opportunity to thank Dr. Dallas Little for his invaluable guidance, support and encouragement throughout this study. I am grateful to him for allowing me to work on this topic. I would like also to thank Dr. Lytton and Dr. Masad for fruitful discussions on the topic of this study. Special thanks are to Dr. Epps and Dr. Cline for serving as committee members and for their input on the thesis.

Special thanks to Ms. Lois Peters from the Department of Civil Engineering at Texas A&M University, and for Ms. Cathy Bryan and Ms. Pam Kopf from the Texas Transportation Institute for their help on many administrative matters.

I appreciate all the support I received from my family in Jordan, my family in College Station (Lina, Ahmad, Danna and Amr), and my friends. This support was essential to keep me motivated and to achieve this goal.

## CHAPTER I

### INTRODUCTION

#### 1.1 Problem Statement

Unbound granular materials are generally used in road pavements as base and subbase layers. The granular materials provide load distribution through aggregate contacts to a level that can be sustained by the subgrade. In pavement design and analysis, the base and subbase layers are often described using the resilient modulus which is the ratio of the dynamic resilient stress to the dynamic resilient strain.

The resilient modulus is often described as a power function of the sum of the principal stresses ( $I$ ). However, it was found that this model has serious limitations as it neglects the effect of shear strain and it can only be used at low strain values in the characterization of granular materials (2). May and Witczak (2) noted that deviatoric stress should be included in the evaluation of the resilient modulus. Uzan (3) developed a model that relates the resilient modulus to the summation of principal stresses and the octahedral stress.

Recent studies have shown that the unbound granular layers exhibit cross-anisotropic properties that are not accounted for in the models used in the practice, and they are not part of the proposed AASHTO 2002 design guide (4, 5, and 6).

---

This thesis follows the style and format of *Transportation Research Record*.

The behavior is caused by the preferred orientation of aggregates in the unbound layers and the compaction forces. The result is base and subbase layers that are stiffer in the vertical direction than in the horizontal direction. The main advantages of using the directional dependency of stiffness are to describe the dilative behaviour of unbound layers and also to reduce/eliminate the unrealistic significant tensile stresses predicted in the granular bases using isotropic models (7). There is a need to further investigate the influence of using different response models (isotropic vs. anisotropic and linear vs. nonlinear) on the performance predictions of asphalt pavements. In addition, there is an urgent need to evaluate the sensitivity of the proposed AASHTO 2002 guide to the properties of unbound layers prior to the use of this guide in the practice.

## **1.2 Thesis Organization**

The thesis is organized in six chapters. Chapter II includes the literature review related to the resilient properties of unbound aggregate bases with emphasis on the anisotropic properties.

In chapter III, a finite element program capable of isotropic and anisotropic as well as linear and nonlinear analyses of unbound layers is used to calculate the deflections of test sections resembling those used in the AASHTO road test. The computations from nonlinear isotropic and anisotropic models of unbound layers are compared to the AASHTO experimental measurements. A total of 246 sections with different layer thicknesses were analyzed. The applied loads varied from 6000 to 30000 psi (single axle load). The material properties for all layers were obtained from a study by Finn et al, (8).

Chapter IV documents the calculations of the permanent deformation and fatigue cracking in typical cross sections of asphalt pavements using the mechanistic-empirical models in the AASHTO 2002. However, the pavements responses that are used in these performance models are calculated using isotropic and anisotropic properties for the unbound layers.

Chapter V presents the sensitivity analysis of the AASHTO 2002 design guide to the characteristics of various base materials. The analysis is conducted for different layer thicknesses, asphalt layer properties, subgrade properties, traffic levels, and environmental conditions. Chapter VI presents the conclusions and recommendations of this research.

### **1.3 Objectives**

The objectives of this study are to:

1. Conduct comparative analysis of flexible pavement response using different models for unbound pavement layers: nonlinear isotropic and nonlinear anisotropic. The results from the different models will be compared with the experimental measurements from the AASHO road test.
2. Evaluate the permanent deformation and fatigue cracking calculated using the performance models in the proposed AASHTO 2002 design guide. These distresses are calculated using pavement responses computed from linear isotropic, nonlinear isotropic, linear anisotropic, and nonlinear anisotropic models for the unbound aggregate layers.

3. Conduct sensitivity analysis of the proposed AASHTO 2002 guide to the properties of the unbound pavement layers.

## CHAPTER II

### LITERATURE REVIEW

#### 2.1 Introduction

Literature review was conducted through information search using electronic databases and documented publications. The information gathered including resilient properties, triaxial testing, resilient models, and permanent deformation models of unbound materials was summarized and documented. This is discussed in this chapter.

Granular materials are commonly used in the unbound bases and subbases of flexible pavements in order to distribute loads, through aggregate contacts and interlocking, such that the subgrade can withstand the applied loads.

The deformation response of granular layers under traffic loading is characterized by recoverable (resilient) deformation and a residual (permanent) deformation. Granular materials are not elastic but the non-recoverable deformation is much smaller than the recoverable deformation. As the number of load repetitions increases the plastic strain due to each load repetition decreases. Therefore, the unbound layers are often described using resilient properties.

The deformation of the granular materials is the result of three mechanisms:

- The consolidation mechanism: The change in the shape and compressibility of particle assemblies,
- Distortion mechanism: characterized by bending, sliding, and rolling of the particles, and

- The crushing and the breaking of the particles which occur when the applied load exceeds the strength of the particles.

## **2.2 Factors Affecting the Resilient Response of Unbound Layers**

It is known that the granular materials and the subgrade soils are nonlinear with an elastic modulus varying with the level of stresses. The resilient response of granular materials is defined by resilient modulus and Poisson's ratio. The factors that influence the behaviour of unbound layers are discussed in this sections (9).

Many studies have shown that the resilient modulus is affected by the confining pressure or the sum of principle stresses and the deviatoric stress. The resilient modulus increases with an increase in the confining pressure, and decreases with an increase in the deviatoric stress. In general, the resilient modulus of unbound materials increases with an increase in density.

Aggregate gradation influences the resilient modulus. Some researchers have shown that the resilient modulus decreases with an increase in the amount of fine materials. It was also shown that the resilient modulus increases with an increase in maximum particle size given that the amount of fines and shape of aggregates remain the same. Stiffness tends to increase with an increase in moisture content below the optimum moisture content. However, beyond the optimum moisture content when the material becomes more saturated and excess pore water pressure is developed the stiffness starts to decline. The effect of moisture change increases as the fine content increases. The resilient modulus tends to increase as aggregate particles become more angular and rougher.

### 2.3 Triaxial Testing of Resilient Properties

The repeated load triaxial test is the method typically used to study the mechanical properties of unbound granular materials. In this test, a deviatoric stress is axially cycled while a constant confining stress is applied. The general relation used to determine the resilient modulus for the unbound granular materials is as follows:

$$M_r = \frac{\Delta(\sigma_1 - \sigma_2)}{\varepsilon_{1,r}} = \frac{\sigma_d}{\varepsilon_{1,r}} \quad (2.1)$$

$$\nu = -\frac{\varepsilon_{3,r}}{\varepsilon_{1,r}} \quad (2.2)$$

Where

$\sigma_1$  = major principal stress,

$\sigma_2$  = minor principal stress,

$\sigma_d$  = deviatoric stress,

$\varepsilon_{1,r}$  = resilient strain in the direction of the major principal stress (axial stress),

$\varepsilon_{3,r}$  = deviatoric strain in the direction of the minor principal stress.

If the repeated load triaxial test is applied with variable confining stresses, the resilient modulus and Poisson's ratio are defined as follows:

$$M_r = \frac{\Delta(\sigma_1 - \sigma_3)\Delta(\sigma_1 + 2\sigma_3)}{\varepsilon_{1,r}\Delta(\sigma_1 + \sigma_3) - 2\varepsilon_{3,r}\Delta\sigma_3} \quad (2.3)$$

$$\nu = \frac{\Delta\sigma_1\varepsilon_{3,r} - \Delta\sigma_3\varepsilon_{1,r}}{2\Delta\sigma_3\varepsilon_{3,r} - \varepsilon_{1,r}\Delta(\sigma_1 + \sigma_3)} \quad (2.4)$$

## 2.4 Models for Resilient Behavior of Unbound Granular Material

Dunlap (10) and Monismith (11) indicated that the resilient modulus increases with an increase in the confining pressure:

$$M_r = K_1 \sigma_3^{K_2} \quad (2.5)$$

where

$K_1$  and  $K_2$  = regression constants,

$\sigma_3$  = the minor principal stress.

Seed (12), Brown and Pell (13) and Hicks (14) found that it is necessary to include the applied axial stress in the analysis so they suggested the following model which is commonly known as K- $\theta$  model:

$$M_r = K_1 \theta^{K_2} \quad (2.6)$$

where

$\theta$  = sum of principal stresses.

The K- $\theta$  model is simple and has been widely used for analysis of stress dependence of material stiffness. However, the model neglects the effect of the shear stress and is therefore applicable only in the range of low strain values. Uzan (3) noticed that the resilient modulus is a function not only of bulk stress but also of the shear stress. Uzan (3) included deviatoric stress and expressed the resilient modulus as follows:

$$M_r = K_1 P_a \left( \frac{I_1}{P_a} \right)^{K_2} \left( \frac{\tau_{oct}}{P_a} \right)^{K_3} \quad (2.7)$$

Where

$\tau_{\text{oct}}$  = octahedral shear stress,

$I_1$  = sum of principal stress ( $\theta$ ),

$P_a$  = atmospheric pressure,

$K_1, K_2,$  and  $K_3$  = regression coefficients that depend on material properties.

Elliot and Lourdesnathan (15) noticed that the Uzan model fits the data very well for pre failure stresses but when the stresses exceeded the static failure the predictions were poor. So they suggested adding the failure term for the previous model:

$$M_r = k_1 \frac{\theta^{K_2}}{10^{A1}} \quad (2.8)$$

where

A = failure term.

Several models have been proposed for the resilient behavior based on decomposing both stresses and strains into volumetric and shear components. Boyce (16) assumed the material to be nonlinear isotropic and proposed the following equations for the volumetric ( $\varepsilon_v$ ) and shear ( $\varepsilon_s$ ) strains:

$$\varepsilon_v = p^A \frac{1}{K} \left[ 1 - \beta \frac{\sigma_d^2}{p^2} \right] \quad (2.9)$$

$$\varepsilon_s = p^A \frac{1}{3G} \left( \frac{\sigma_d}{p} \right) \quad (2.10)$$

Where

p = hydrostatic stress,

G = shear modulus,

K = bulk modulus.

Brown and Pappin (17) proposed the following relationships for the volumetric and shear strains:

$$\varepsilon_v = \delta \left[ \left( \frac{P}{A} \right)^B \left( 1 - C \left( \frac{\sigma_d}{p} \right)^2 \right) \right] \quad (2.11)$$

$$\varepsilon_s = \delta D \left[ \frac{\sigma_d}{P + E} \right] \left[ \frac{\sqrt{P_r^2 + \sigma_d^2}}{p_m} \right]^F \quad (2.12)$$

Where

$\varepsilon_v$  = recoverable volumetric strain,

$\varepsilon_s$  = shear strain,

$P$  = mean normal stress,

$\sigma_d$  = deviatoric Stress.

Several studies (Tutumluer, (4); Tutumluer and Thompson, (18), Hornyh et al. (19) suggested that the use of anisotropic models better represent the behaviour of granular materials.

The Boyce model was modified by Hornyh (19) in order to account for the effect of anisotropy. The mathematical expressions of the anisotropic model are as follows:

$$\varepsilon_v = \frac{P^{*A}}{P_0^{A-1}} \left[ \frac{\gamma + 2}{3K_1} + \frac{A-1}{18G_1} (\gamma + 2) \left( \frac{q^*}{p^*} \right)^2 + \frac{\gamma - 1}{3G_1} \left( \frac{q^*}{p^*} \right) \right] \quad (2.13)$$

$$\varepsilon_s = \frac{2}{3} \frac{P^{*A}}{P_0^{A-1}} \left[ \frac{\gamma - 1}{3K_1} + \frac{A-1}{18G_1} (\gamma - 1) \left( \frac{q^*}{p^*} \right)^2 + \frac{2\gamma + 1}{6G_1} \left( \frac{q^*}{p^*} \right) \right] \quad (2.14)$$

Triaxial testing was conducted using a machine capable of applying dynamic loads in the axial and radial directions (18). The results obtained from this test showed definite directional dependency (anisotropy) of aggregate moduli. The resilient moduli in the vertical and radial directions varied with the applied stress states. It was noticed that the vertical modulus in the vertical direction is more than that for horizontal direction for unbound materials. However, this relationship was reversed in the case of sandy gravel with high fines content and if the specimen was compacted at the wet side of optimum.

Five cross-anisotropic material properties are needed to define an anisotropic material under conditions of axial symmetry: the horizontal resilient modulus ( $M_R^H$ ), the vertical dynamic modulus ( $M_R^V$ ), the shear modulus ( $G_R$ ), the horizontal Poisson's ratio ( $\nu_H$ ), and the vertical Poisson's ratio ( $\nu_V$ ). These properties are defined as follows:

$$M_R^V = \frac{\sigma_d}{\varepsilon_{vertical}} \quad (2.15)$$

$$M_R^H = \frac{\sigma_3}{\varepsilon_{horizontal}} \quad (2.16)$$

$$G_R = \frac{\sigma_d}{2(\varepsilon_{vertical} - \varepsilon_{horizontal})} \quad (2.17)$$

$$\nu_H = -\frac{\varepsilon_{horizontal\_2}}{\varepsilon_{horizontal\_1}} \quad (2.18)$$

$$\nu_V = -\frac{\varepsilon_{horizontal}}{\varepsilon_{vertical}} \quad (2.19)$$

$\varepsilon_{\text{horizontal}_1}$  is the applied horizontal strain, and  $\varepsilon_{\text{horizontal}_2}$  is the measured horizontal strain  $90^\circ$  from the applied horizontal strain.

$$M_R^V = K_1 P_a \left( \frac{I_1}{P_a} \right)^{K_2} \left( \frac{\sigma_d}{P_a} \right)^{K_3} \quad (2.20)$$

$$M_R^H = K_4 P_a \left( \frac{I_1}{P_a} \right)^{K_5} \left( \frac{\sigma_d}{P_a} \right)^{K_6} \quad (2.21)$$

$$G_R = K_7 P_a \left( \frac{I_1}{P_a} \right)^{K_8} \left( \frac{\sigma_d}{P_a} \right)^{K_9} \quad (2.22)$$

As it was mentioned before the advantage of modeling granular materials using cross anisotropic nonlinear elasticity is to predict the dilative granular material behaviour (20). Figure (2.1) shows the variation of principal strain ratios with increasing major to minor principal stress ratios. Any value less than 2 for the stress ratio corresponds to the case of elastic dilation. The nonlinear anisotropic model matches very well the experimental values. On the other hand, under the assumption of linear isotropy, modeling of the dilative behavior could be achieved when the Poisson's ratio is more than 0.5.

## 2.5 Models for Permanent Deformation of Unbound Granular Material

The deformational response of the granular materials can be defined under repeated, traffic-type loading by a resilient response which is important for load carrying ability and permanent strain response which characterizes the long-term performance of the pavement and rutting phenomenon. Few studies have been conducted to model the permanent deformation of granular materials.

Several factors affect the plastic behavior in the unbound granular materials, these factors include, stress, principal stress reorientation, number of load applications, moisture content, stress history, density and fine contents, grading and aggregate type (21).

There are several models used to characterize the permanent deformation properties and to predict the permanent strain in the unbound granular materials.

Barksdale (22) found by using the repeated load triaxial tests with  $10^5$  load applications that the accumulation of permanent axial stain was proportional to the logarithm of the number of load cycles and expressed as follows:

$$\varepsilon_{1,P} = a + b \log(N) \quad (2.23)$$

where

N = number of load repetitions,

$\varepsilon_{1,P}$  = permanent strain,

a and b = regression parameters.

Bonaquist and Witzak (23) developed a model based on the flow theory of plasticity. This model defines the magnitude of the permanent strain occurring during the first cycle of loading. Under repeated loading the permanent strain at any load cycle can be expressed as a power function of permanent strain during the first load cycle. The total permanent strain will be the sum of the permanent strain in each cycle.

$$\varepsilon_{1,P} = \sum \varepsilon_N = \sum \frac{1}{N^h} \varepsilon_i \quad (2.24)$$

where

$\varepsilon_1$  = permanent strain in the first load cycle,

$\varepsilon_N$  = permanent strain for load cycle N.

The Hyperbolic model developed by Duncan and Chang (24) is used to predict the plastic strain by using static triaxial tests. The results from this test are then used to relate the permanent axial strain to the ratio of repeated deviator stress and constant confining pressure. The model is expressed as:

$$\varepsilon_{1,p} = \frac{\sigma_d / a \sigma_3^b}{1 - \left[ \frac{(R_{f_q}) / 2 (C \cos \phi + \sigma_3 \sin \phi)}{(1 - \sin \phi)} \right]} \quad (2.25)$$

where

$\varepsilon_p$  = the axial plastic strain,

C = cohesion,

$\phi$  = angle of internal friction,

R = the ratio of measured strength to ultimate hyperbolic strength.

Models developed by Tseng and Lytton (25) are used to estimate the permanent deformation of asphalt, base and subgrade materials. The basic relationship is:

$$\delta_a(N) = \left( \frac{\varepsilon_0}{\varepsilon_r} \right) e^{-\left(\frac{\rho}{N}\right)^\beta} \varepsilon_v h \quad (2.26)$$

where

$\delta_a$  = permanent deformation for layer/sublayer,

$\varepsilon_v$  = average vertical resilient strain in the layer/sublayer as obtained from the primary response model,

$h$  = thickness of layer/sublayer,

$\varepsilon_r$  = resilient strain imposed in laboratory test to obtain material properties  $\varepsilon_0$ ,  $\rho$  and  $\beta$ .

The ratio  $\frac{\varepsilon_0}{\varepsilon_r}$ ,  $\beta$  and  $\rho$  are estimated according to the type of materials

investigated. For granular base, the ratio can be estimated using the following form:

$$\log\left(\frac{\varepsilon_0}{\varepsilon_r}\right) = .80978 - .06626W_c - .003077\sigma_\theta + .000003E_r \quad (2.27)$$

$$\log\beta = -.919 + .03105W_c + .001806\sigma_\theta - .0000015E_r \quad (2.28)$$

$$\log\rho = -1.78667 + 1.45062W_c + .003784\sigma_\theta^2 - .002074W_c^2\sigma_\theta - .0000105E_r \quad (2.29)$$

For subgrade, the model parameters can be estimated using the following relationships:

$$\log\left(\frac{\varepsilon_0}{\varepsilon_r}\right) = -1.69867 + .09121W_c - .11921\sigma_d + .91219\log E_r \quad (2.30)$$

$$\log\beta = -.973 - .0000278W_c^2\sigma_d + .017165\sigma_d - .00000338W_c^2\sigma_\theta \quad (2.31)$$

$$\log\rho = 11.009 + .0000681W_c^2\sigma_d - .4026\sigma_d + .00000545W_c^2\sigma_\theta \quad (2.32)$$

The above equations are modified from the ones published by Tseng and Lytton. It was found, based on discussion with Dr.Lytton that sign errors where in the paper by Tseng and Lytton.

Some researchers developed computational procedures for pavement analysis based on the Shakedown theory (26). According to the Shakedown theory, if the applied load exceeds a limiting value called a shakedown load the pavement will show a progressive accumulation of plastic strains under repeated loading. On the other hand if the applied loads are lower that the shakedown limit, the pavement will be able to adapt

the loads. So the response for the pavement will be totally resilient under the load applications.

The Vesys computer program is used to predict the rut depth based on the assumption that the permanent strain is proportional to the resilient strain by

$$\varepsilon_p(N) = \varepsilon \mu N^{-\alpha} \quad (2.33)$$

where

$\varepsilon_p(N)$  = permanent or plastic strain due to a single load application at Nth application,

$\varepsilon$  = elastic or resilient strain at the 200th repetition,

N = load application number,

$\mu$  = permanent deformation representing the constant of proportionality between permanent and elastic strain,

$\alpha$  = the permanent deformation indicating the rate of decrease in permanent strain with number of load applications.

## **CHAPTER III**

# **SENSITIVITY ANALYSIS OF PAVEMENT RESPONSE USING DIFFERENT STRUCTURAL MODELS AND COMPARISON WITH AASHO ROAD MEASUREMENTS**

### **3.1 Introduction**

This chapter includes a comparison between the pavement deflections calculated using isotropic and anisotropic nonlinear models for the unbound layers and the field deflection measurements in the AASHO road test. The comparison is conducted based on deflection measurements rather than the measured performance in order to the comparison not to be affected by the assumptions made in the empirical transfer functions typically used in performance predictions.

The asphalt layer is assumed to be linear isotropic while the base and subbase layer are modeled using nonlinear isotropic and nonlinear anisotropic properties. The subgrade is modeled using nonlinear isotropic properties. The analysis includes a total of 246 sections with different layer thicknesses. The applied loads in the AASHO test varied from 6000 to 30000psi (single axle load). The material properties for all layers are obtained from the experimental measurements by Finn et al. (8).

### **3.2 AASHO Road Test**

#### **3.2.1 Background about the AASHO Road Test**

The AASHO Road test near Ottawa, Illinois, was performed over a two year period to develop a design methodology for asphalt and concrete pavements (27, 28). The test

facilities consisted of 4 major loops numbered from 3 through 6 and two smaller loops. All vehicles had the same axle arrangements-axle load combinations to any one traffic lane of loops 2 through 6. The same materials were used in all the major loops as listed in Table 3.1.

TABLE 3.1 Description of Materials Used in the Major Loops of the AASHO Road Test

Layer	Material
Hot Mix Asphalt	<ul style="list-style-type: none"> <li>• Crushed limestone coarse aggregate</li> <li>• Natural siliceous coarse sand</li> <li>• Mineral filler which was limestone dust</li> <li>• Penetration Grade asphalt cement (85-100 pen)</li> </ul>
Base	Crushed Dolomitic Limestone
Subbase	Sand-Gravel mixture
Subgrade	A-6

The loops were subjected to traffic for more than two years. The traffic was operated at 35 mph on the test sections over 18 hrs with periods of 40 minutes each day for 6 days a week. The traffic was extended to 7 days a week during the first 6 months of 1960.

The major loops included a total of 468 sections. Each test section was 12-ft wide, and most of them were 100 or 160 ft long. Each loop included pavement sections with three different thicknesses of asphalt concrete surfacing, three different thicknesses of crushed limestone base, and three different thicknesses of sand-gravel subbase.

The applied axle load over the test sections ranged from a 2000 lb single axle load in one lane and a 6000 lb single axle load in the other lane in loop 2. Loop 6 was subjected to a 30000 lb single axle load in one lane and a 48000 lb tandem axle load in the other. Table 3.2 summarizes the variables in the major sections.

TABLE 3.2 Materials and Loads Used in the AASHO Test

Item	Loop					
	1	2	3	4	5	6
Test axle loading (Ib)	No traffic	2,000 S	12,000 S	18,000 S	22,400 S	30,000 S
		6,000 S	24,000 T	32,000 T	40,000 T	48,000 T
Factorial test sections	48	44	60	60	60	60
Special study sections	16	24	24	24	24	24
Asphalt Concrete Surfacing Thicknesses (in)	1,3,5	0,1,2,3	2,3,4	3,4,5	3,4,5	4,5,6
Base thicknesses (in)	0,6	0,3,6	0,3,6	0,3,6	3,6,9	3,6,9
Subbase thicknesses (in)	0,8,16	0,4	0,4,8	4,8,12	4,8,12	8,12,16

### 3.2.2 Field Deflection Measurements and Material Properties

#### 3.2.2.1 Field Deflection Measurements

Deflection measurements of the pavement surface are important for the evaluation of the performance of a flexible pavement structure and rigid pavement load transfer. The surface deflection is a function of many factors used in the design of the pavement such as traffic (type and volume), pavement structural section, temperature, and moisture. Thus, many characteristics of a flexible pavement can be determined by measuring its

deflection in response to load. The advantage of using deflection to compare with analytical solutions is that no empirical transfer functions are used in this comparison as is the case in performance predictions.

Surface deflection is measured as a pavement surface's vertical deflected distance as a result of an applied (either static or dynamic) load. In the AASHO test, the deflection of a pavement surface was measured using the Benkelman beam under vehicle wheels moving at creep speeds (approximately 2mph). The Benkelman Beam consists of a simple lever arm supported by 3 legs (Figure 3.1). The Benkelman Beam was used with a loaded truck - typically 80 kN (18,000 lb) on a single axle with dual tires inflated to 480 to 550 kPa (70 to 80 psi). Tip of measuring arm was placed between the dual tires of a truck. As the truck moved at the creep speed, the device recorded the rebound deflection of the pavement surface. The measured deflection for each test consisted of the mean of four measurements; two in the inner and two in the outer wheel path.

FIGURE 3.1 A schematic of the Benkelman beam.

Two series of deflection measurements were conducted in the AASHO road test. The first series included the deflections in the fall of 1958, while the second series included the deflections in the spring of 1959. The fall period was selected because the highway was completed and opened to traffic at that time. The spring period was selected because there was a big chance of the distress occurrence that time due to the higher moisture contents of the base and subbase that existed in the spring. Table 3.3 shows the loads used in the deflection measurements.

TABLE 3.3 Loads Used in Deflection Studies

Loop	Lane	Single Axle Load (Kips)

### 3.2.2.2 Seasonal Material Characterization

Since the performance of the pavements varies from season to season, it was necessary to analyze the AASHO road test pavement in different seasons (29). Finn et al. (8) characterized the properties of the materials used in the AASHO road test including the asphalt surfacing, base, subbase and subgrade. The evaluation of the seasonal material properties was conducted using laboratory triaxial testing. The resilient moduli for the base and subbase materials were expressed as function of the first stress invariant, while the subgrade materials were modeled as a function of the deviatoric stress.

The modulus of the asphalt concrete was measured at the average temperature of the AASHO road test location during the traffic testing. The resilient moduli of the base materials were measured at density values representing the construction values, and using three different water contents to take into account the seasonal variation (water content = 4.2%, 5.6%, and 1.5%).

The subbase material modulus was measured at the optimum water content (3.8%) and at the saturation water content (6.4%). The subgrade modulus was determined using a trial and error procedure such that the calculated surface deflections using a linear elastic program had the best match with field measurements. The material moduli are shown in Table 3.4. The Poisson's ratio was assumed constant for each material, and the values in Table 3.5 were assigned for the different layers.

TABLE 3.4 Elastic Moduli of AASHO Road Test Materials

Seasons	Material Moduli			
	Asphalt concrete	Base	Subbase	Subgrade
	psi (kPa)	psi (kPa)	psi (kPa)	psi (kPa)
Spring	$0.71 \times 10^6$ ( $4.9 \times 10^6$ )	$3200 \theta^{0.6}$ ( $6900 \theta^{0.6}$ )	$4600 \theta^{0.6}$ ( $10000 \theta^{0.6}$ )	$8000 \sigma_d^{-1.06}$ ( $427000 \sigma_d^{-1.06}$ )
Fall	$0.45 \times 10^6$ ( $3.1 \times 10^6$ )	$4000 \theta^{0.6}$ ( $8700 \theta^{0.6}$ )	$5400 \theta^{0.6}$ ( $11700 \theta^{0.6}$ )	$27000 \sigma_d^{-1.06}$ ( $1440000 \sigma_d^{-1.06}$ )
Summer	$0.23 \times 10^6$ ( $1.6 \times 10^6$ )	$3600 \theta^{0.6}$ ( $7800 \theta^{0.6}$ )	$5000 \theta^{0.6}$ ( $10800 \theta^{0.6}$ )	$18000 \sigma_d^{-1.06}$ ( $960000 \sigma_d^{-1.06}$ )
Winter	$1.7 \times 10^6$ ( $11.7 \times 10^6$ )	50000 (34500)	50000 (345000)	50000 (345000)

### 3.3 Pavement Analysis

A finite element program was used to calculate the deflections at the surface of the pavement by using the materials properties given in Tables 3.4 and 3.5. Two models were used in the finite element program to describe the base and subbase layers; nonlinear isotropic and nonlinear anisotropic. The results were compared with the experimental deflection measurements.

The finite element program allows the computation of the resilient response of flexible pavement, such as stress, strain and deformation at any location in the pavement. The program accounts for nonlinear and anisotropic elastic properties of all pavement layers. The program uses a typical axisymmetric finite element mesh as shown in Figure 3.2. The mesh used in this analysis has 50 in width with 9 columns while the length is 100 in with 16 rows. The total number of elements is 144. Each element has 8 nodes. The applied pressure is 75 psi which is equivalent to the pressure used in the Benkelman device in the AASHO road test to measure the surface deflection. The loading radius depends on the applied load which was different for the different loops.

It is known that the modulus of the unbound granular materials is stress sensitive and changes through the layer so the modulus of the untreated materials at any point in the layer is a function of stress. The properties are the same in all directions (isotropic). The resilient modulus is calculated as:

$$M_r = K_1 P_a \left( \frac{I_1}{P_a} \right)^{K_2} \left( \frac{\tau_{oct}}{P_a} \right)^{K_3} \quad (3.1)$$

where

$I_1$  = first stress invariant (Sum of principal stresses),

$\tau_{oct}$  = octahedral shear stress,

$P_a$  = atmospheric pressure.

$K_1$ ,  $K_2$  and  $K_3$  used in the finite element model are calculated based on the measured material properties given in Table 3.4 for the spring and fall seasons.

In the anisotropic model, equations similar to Eq. 3.1 are used to express the vertical modulus, horizontal modulus, and shear modulus. The moduli are modeled from the triaxial stress states using the following equations:

$$M_R^V = K_1 P_a \left( \frac{I_1}{P_a} \right)^{K_2} \left( \frac{\sigma_d}{P_a} \right)^{K_3} \quad (3.2)$$

$$M_R^H = K_4 P_a \left( \frac{I_1}{P_a} \right)^{K_5} \left( \frac{\sigma_d}{P_a} \right)^{K_6} \quad (3.3)$$

$$G_R = K_7 P_a \left( \frac{I_1}{P_a} \right)^{K_8} \left( \frac{\sigma_d}{P_a} \right)^{K_9} \quad (3.4)$$

FIGURE 3.2 Finite element mesh for pavement analysis.

The finite element program requires the  $K_1$ ,  $K_2$ ,  $K_3$ ,  $n$ ,  $m$  and  $\mu$  parameters:

$$n = \frac{M_R^H}{M_R^V} \quad (3.5)$$

$$m = \frac{G_{xy}}{M_R^V} \quad (3.6)$$

$$\mu = \frac{\nu_{xx}}{\nu_{xy}} \quad (3.7)$$

$\nu_{xx}$  is the horizontal Poisson's ratio, and  $\nu_{xy}$  is the vertical Poisson's ratio.

In this study, the base and subbase layer are assumed to be either nonlinear isotropic or nonlinear anisotropic. In the isotropic approach, the modular ratios ( $n$  and  $\mu$ ) are set to 1. In the anisotropic analysis, the  $n$  value is taken to be 0.5, 0.4 and 0.3, while  $\mu$  is set to 1.5. These values are selected to represent experimental measurements for a wide range of aggregates at the Texas Transportation Institute (5, 30). By assuming the Poisson's ratio in the base and subbase layer to be equal 0.4, the  $m$  value can be determined by using the following equation.

$$m = \frac{1}{2(1 + \nu_{xy})} \quad (3.8)$$

The asphalt layer is modeled as linear isotropic, and the materials properties  $K_2$  and  $K_3$  are set to zero. The subgrade is modeled by nonlinear isotropic properties. Table 3.6 shows a summary of the input data used in the FEM

TABLE 3.6 A Summary of the Input Data Used in the FEM Program (LIS: Linear Isotropic, NIS: Nonlinear Isotropic, NAN: Nonlinear Anisotropic, NIS: Nonlinear Isotropic)

### **3.4 Comparison Between the FEM Calculations and Measurements**

A comparative analysis was conducted between the finite element predictions and the measured deflections in the AASHO road sections. The finite element program was used to calculate the deflections at the surface of 246 different pavement sections. The material properties for 134 sections represented the fall season, while the remaining 112 sections represented the spring season. These predicted deflections were then compared with the deflections measured in the AASHO Road test. The sections used for this study were from loop 2 through loop 6 with single axle loads that ranged from 6 to 30 kip.

Figures 3.3-3.6 show the relationships between the field measurements in the fall season and the finite element results using either isotropic or anisotropic material properties. The comparisons with the measurements from the spring season are shown in Figures 3.7-3.10, and the results combined for both seasons are shown in Figures 3.11-3.14. Deflections calculated using isotropic material properties tend to be smaller than the experimental measurements. As the anisotropy increases ( $n$  value decreases), the calculated deflections become closer to the measurements and the accuracy of the prediction increases. In general, the finite element predictions are closer to measurements in the fall season than in the spring season.

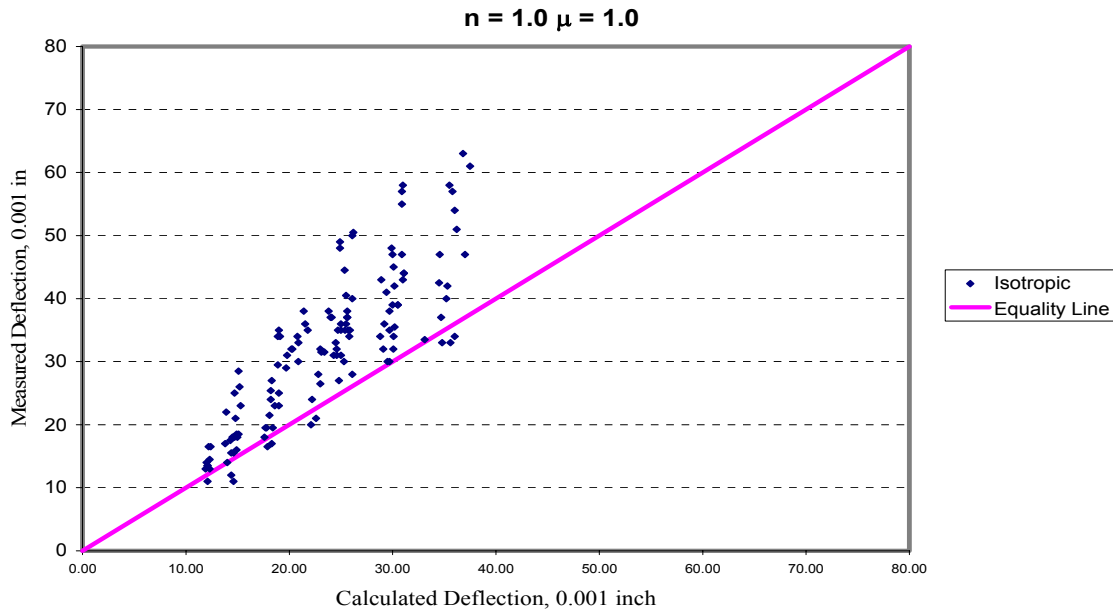

FIGURE 3.3 Measured versus calculated deflections for the fall season using isotropic properties.

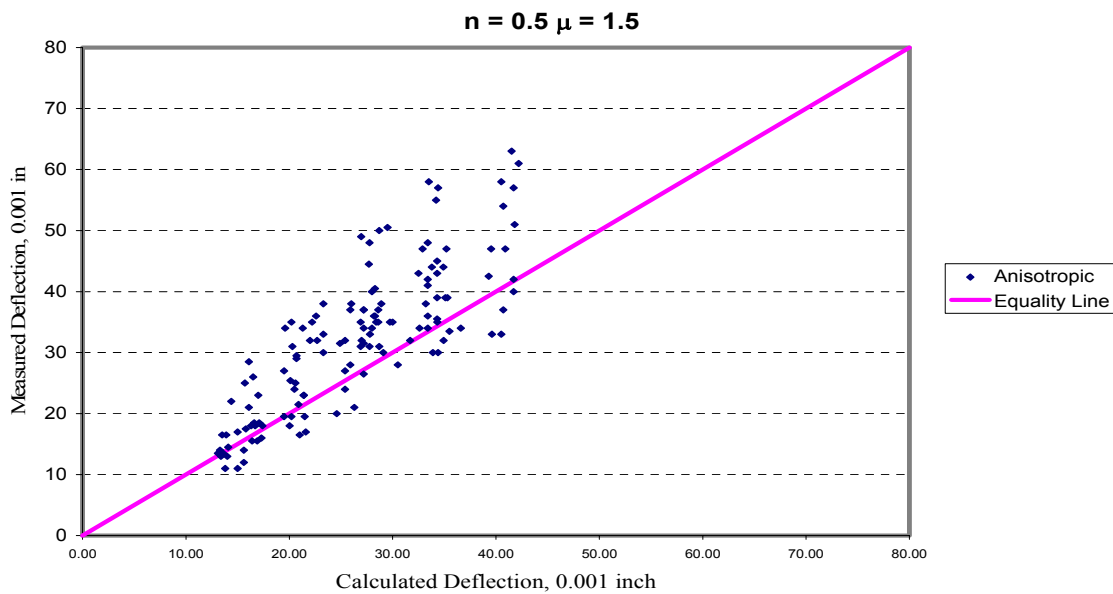

FIGURE 3.4 Measured versus calculated deflections for the fall season using anisotropic properties with  $n = 0.5$ .

FIGURE 3.5 Measured versus calculated deflections for the fall season using anisotropic properties with  $n = 0.4$ .

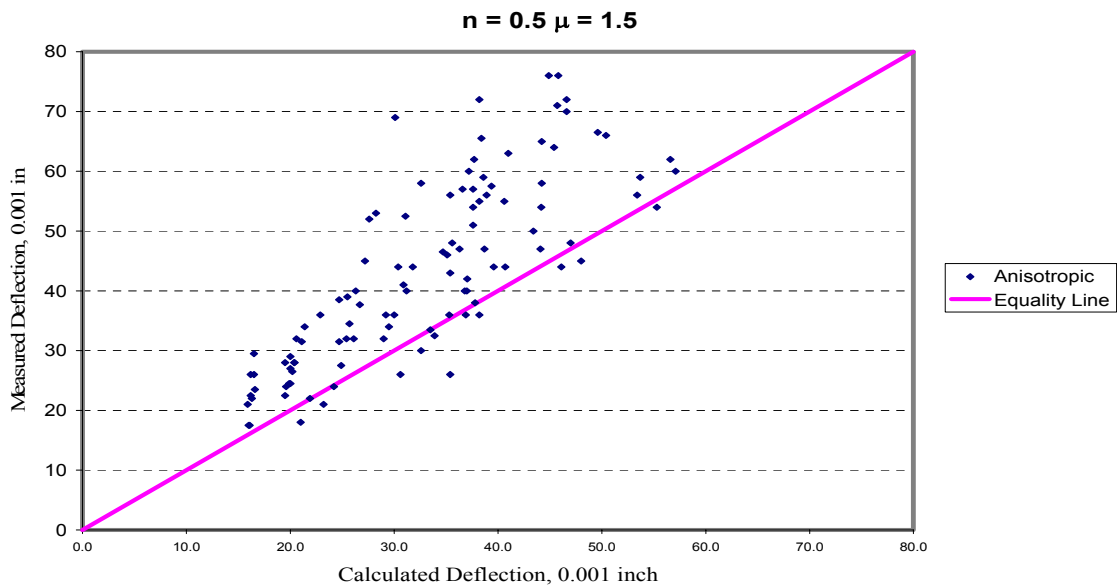

FIGURE 3.8 Measured versus calculated deflections for the spring season using anisotropic properties with  $n = 0.5$ .

FIGURE 3.9 Measured versus calculated deflections for the spring season using anisotropic properties with  $n = 0.4$ .

FIGURE 3.10 Measured versus calculated deflections for the spring season using anisotropic properties with  $n = 0.3$ .

FIGURE 3.11 Measured versus calculated deflections for the spring and fall seasons using isotropic properties.

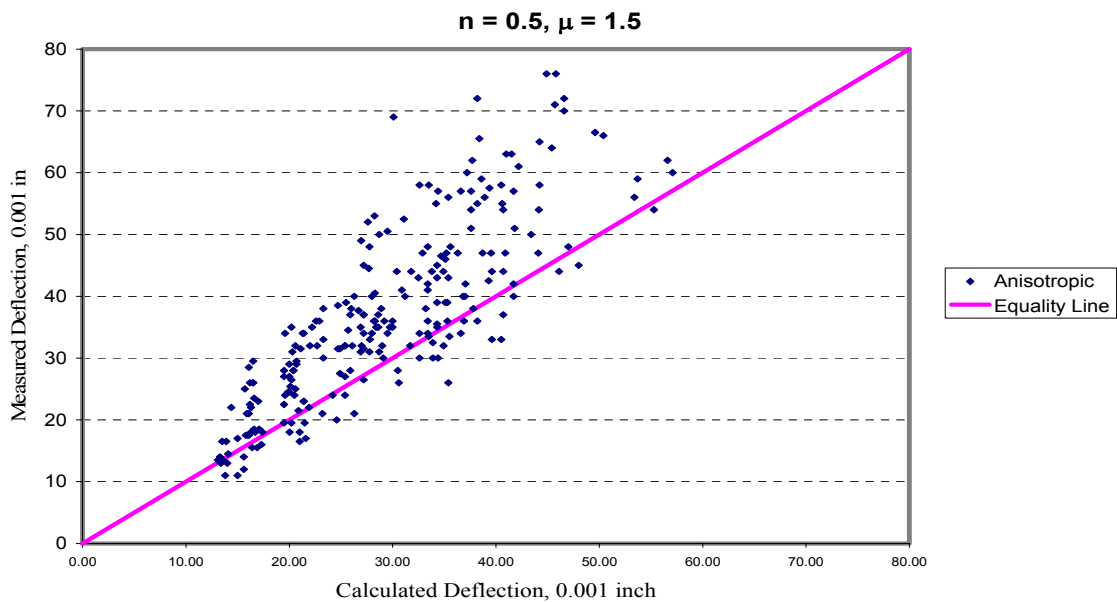

FIGURE 3.12 Measured versus calculated deflections for the spring and fall season using anisotropic properties with  $n = 0.5$ .

FIGURE 3.13 Measured versus calculated deflections for the spring and fall season using anisotropic properties with  $n = 0.4$ .

FIGURE 3.14 Measured versus calculated deflections for the spring and fall season using anisotropic properties with  $n = 0.3$ .

The accuracy of the calculations in predicting the measurements was studied by calculating the percentage of error which is the absolute difference between the calculated and measured values divided by the measured value. The cumulative distribution function of errors is shown in Figures 3.15-3.17. The y axis represents the percentage of data points with an error equal to or less than the corresponding value on the x axis. The results clearly show that the anisotropic model reduces the percentage of errors. This point can also be shown in Figures 3.18-3.20, which show the number of data points that belong to different error levels. Again, it can be seen that the number of data points shift from high error ranges to small error ranges as anisotropy increases.

### 3.5 Summary of Findings

In this chapter, a finite element program was used to calculate deflections of sections resembling the AASHO road test. These calculations were compared to the field experimental measurements. The following points summarize the findings:

- Anisotropy was modeled by the ratio of the horizontal modulus to vertical modulus. The percentage of error between predictions and measurements decreased as the anisotropy increased.
- The FEM predictions correlated the best with the experimental measurements when the horizontal modulus was about 30% of the vertical modulus.
- The predictions matched the AASHO measurements in the fall season better than the measurements in the spring season. As reported in the AASHO experiment, distresses were detected in the spring season that might have caused the response to deviate from the elastic solutions used in the FEM.

## **CHAPTER IV**

### **ANALYSIS OF FLEXIBLE PAVEMENT RUTTING AND FATIGUE CRACKING USING ISOTROPIC AND ANISOTROPIC RESPONSE MODELS**

#### **4.1 Introduction**

This chapter presents predictions of permanent deformation and fatigue cracking based on the mechanistic-empirical models used in the AASHTO 2002. These models utilize elastic stress and strain values, which are calculated in this chapter using a finite element program with the base course represented by linear isotropic, nonlinear isotropic, linear cross-anisotropic or nonlinear cross-anisotropic properties. Comparisons between the performance predictions of rutting and fatigue cracking using these different models are reported in this chapter.

#### **4.2 Fatigue Cracking Models in the AASHTO 2002 Guide**

Fatigue cracking is one of the most important distresses occurring in flexible pavements. The repeated traffic induces tensile and shear stresses in the bound layer. The repeated load initiates cracks at the point of critical tensile stress. The location of the critical tensile stress depends on the stiffness of the layer.

It is typically assumed that the fatigue cracking normally occurs at the bottom of the asphalt layer and propagates to the surface. In order to predict the allowable number of load repetitions for fatigue cracking to occur in the flexible pavement, the tensile strain at the bottom of the HMA layer is considered as the critical strain. This type of

cracking (bottom up cracking) is actually due the bending action of the pavement layer. However most recent studies show that fatigue cracking may initiate from the top and propagate down (top-down). The top-down cracking is caused by large contact pressures at the tire edge-pavement interface where the top layer of the pavement has been oxidized (6). In this case, the critical point for the tensile strain will be at the surface of the layer or at 0.5in from the top (6). The different versions of the AASHTO 2002 released until the point of the preparation of this thesis included two models for fatigue which are discussed herein.

The model used to find the allowable number of load repetition has the following form:

$$N_f = Ck_1 \left( \frac{1}{\varepsilon_t} \right)^{k_2} \left( \frac{1}{E} \right)^{k_3} \quad (4.1)$$

$$= Ck_1 (\varepsilon_t)^{-k_2} (E^*)^{-K_3} \quad (4.2)$$

where

$N_f$  = number of repetitions to fatigue cracking,

$\varepsilon_t$  = tensile strain at the critical location,

$E$  = stiffness of the material,

$k_1, k_2, k_3$  = laboratory calibration parameters,

$C$  = laboratory to field adjustment factor.

The fatigue model in the AASHTO 2002 design guide released on December 2002 is based on the Shell Oil fatigue model. The most important terms in this model

are the stiffness of the asphalt layer and the tensile strain at the point of critical location. The critical location may be at the top of the layer for the top-down cracking or at the bottom for the bottom-up cracking.

Two types of controlled loading are used in the laboratory for fatigue cracking the constant stress and constant stain. Constant stress loading is considered applicable when the thickness of the layer is more than 8 inches, while constant strain is applicable for thin layers less than two inches. Shell Oil has developed equations to predict fatigue cracking for these two cases. These equations are summarized below:

$$\text{Constant Strain: } N_f = A_f \left[ 0.17PI - 0.0085PI(V_b) + 0.0454V - 0.112 \right]^5 \varepsilon_t^{-5} E^{-1.8} \quad (4.3)$$

$$\text{Constant Stress: } N_f = A_f \left[ 0.0252PI - .00126PI(V_b) + 0.00673V_b - 0.0167 \right]^5 \varepsilon_t^{-5} E^{-1.4} \quad (4.4)$$

where

PI = penetration index,

$V_b$  = volume of bitumen.

Since the thickness for the asphalt layer could be between 2 and 8 inches which is not included in these equations, a new equation is developed in the AASHTO 2002 design guide to take into account the intermediate thickness (between 2 and 8 inches) based on equations 4.3 and 4.4. The generalized Shell Oil fatigue equation is as follows:

$$N_f = C \left( 1 + \frac{13909E^{-0.4} - 1}{1 + \exp^{(1.354h_{ac} - 5.408)}} \right) \left( 0.0252PI - 0.00126PI(V_b) + 0.00673V_b - 0.0167 \right)^5 \left( \frac{1}{\varepsilon_t} \right) \left( \frac{1}{E^*} \right)^{-1.4} \quad (4.5)$$

$$F'' = 1 + \frac{13909E^{-0.4} - 1}{1 + \exp^{(1.354h_{ac} - 5.408)}} \quad (4.6)$$

$$K_{1\alpha} = \left[ 0.0252PI - 0.00126PI(V_b) + 0.00673V_b - 0.0167 \right]^5 \quad (4.7)$$

where

C = laboratory to field adjustment factor; with a default value of 1.0,

$h_{ac}$  = thickness of the asphalt layer,

$\varepsilon_t$  = tensile strain,

E = stiffness of the material,

PI = penetration index,

$V_b$  = volume of bitumen.

The fatigue model used in the AASHTO 2002 design guide released in November 2003 was based on the Asphalt institute method. However, the equations were modified using calibration factors based on data collected from 82 LTPP sections located in 24 states, and to accommodate pavements with different thicknesses. The model has the form in Equations 4.8 – 4.12:

$$N_f = \beta_{f1} k_1 (\varepsilon_t)^{-\beta_{f2} k_2} (E^*)^{-\beta_{f3} k_3} \quad (4.8)$$

$$N_f = 0.00432 * k_1' * C \left( \frac{1}{\varepsilon_t} \right)^{3.9492} \left( \frac{1}{E} \right)^{1.281} \quad (4.9)$$

$$C = 10^M \quad (4.10)$$

$$M = 4.84 \left( \frac{V_b}{V_a + V_b} - 0.69 \right) \quad (4.11)$$

$$k_1' = \frac{1}{0.000398 + \frac{0.003602}{1 + e^{(11.02 - 3.49 * h_{ac})}}} \quad (4.12)$$

where

$\beta_{f1}, \beta_{f2}, \beta_{f3}$  = calibration parameters,

$V_a$  = percent air voids,

$V_b$  = effective binder content,

$h_{ac}$  = total thickness of the asphalt layer,

$k_1'$  = correction for different asphalt layer thickness effects.

### **4.3 Analysis of Fatigue Cracking Using Isotropic and Anisotropic Models**

The base layer and the asphalt mix are modeled using linear isotropic, nonlinear isotropic, linear cross-anisotropic or nonlinear cross anisotropic properties. The parameters  $K_1$ ,  $K_2$ ,  $K_3$ ,  $n$ ,  $m$  and  $\mu$  in Eqs. 3.2-3.8 for the different pavement layers are shown in Table 4.1.  $\nu_{xx}$  is the horizontal Poisson's ratio, and  $\nu_{xy}$  is the vertical Poisson's ratio. The linear isotropic properties are determined by taking  $K_2$  and  $K_3$  to be zero, while  $n$  and  $m$  are assigned to unity. Six sections are used in the analysis. Sketches of these sections are shown in Figure 4.1.

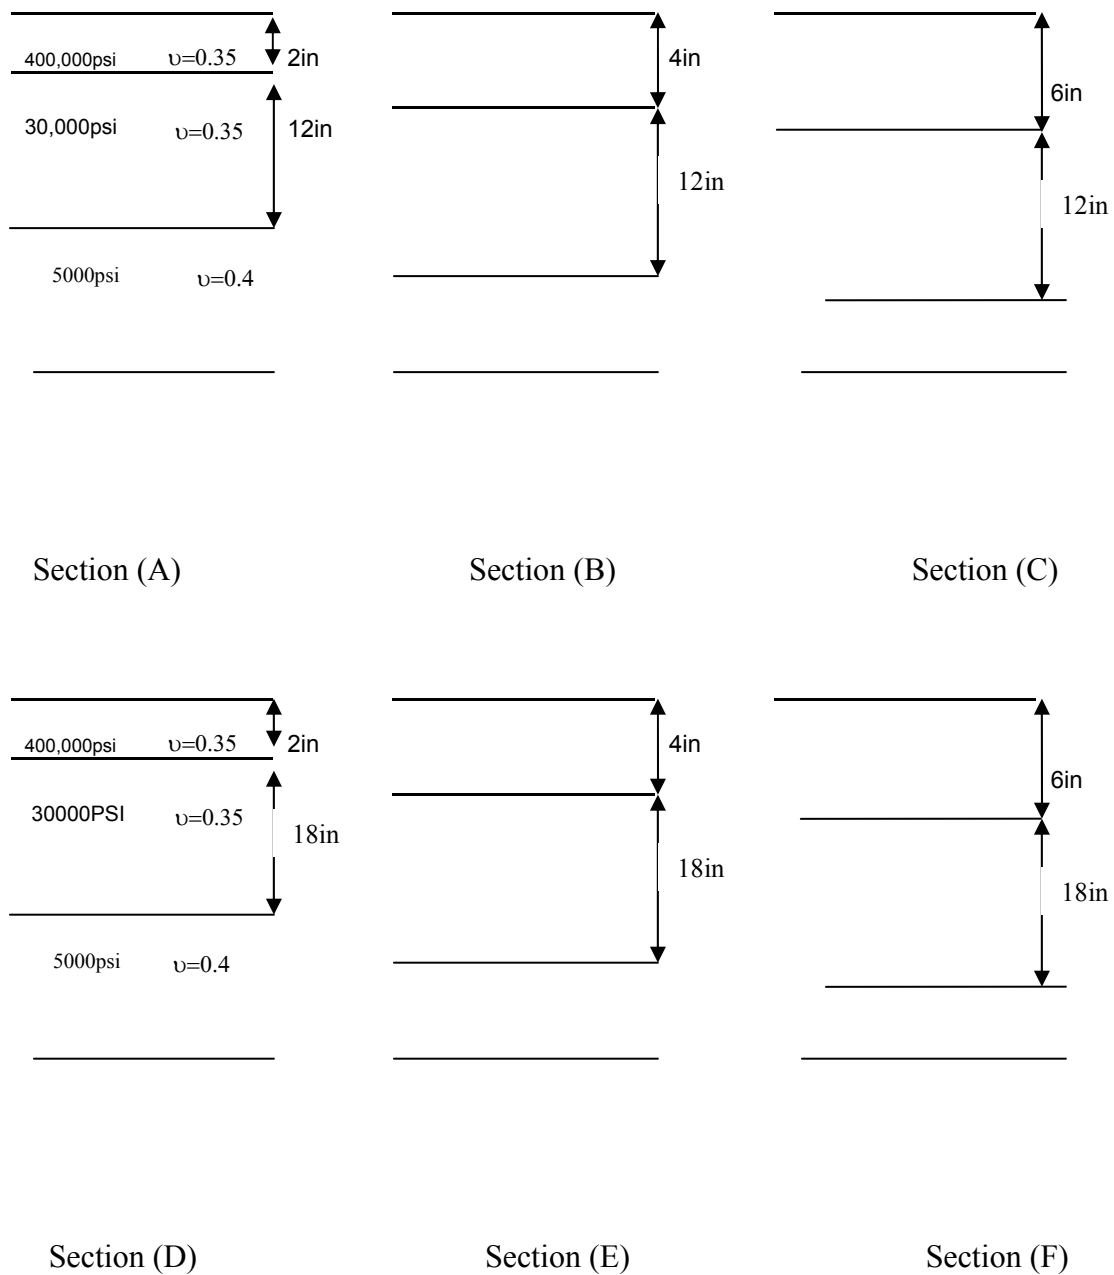

FIGURE 4.1 The sections used in the analysis.

The fatigue analysis is conducted using the Shell model and Asphalt Institute model calibrated in the AASHTO 2002 design guide. The tensile strain at the bottom of the HMA layer was considered as the critical strain for bottom-top cracking.

The Shell equation was used with typical values for the penetration index (0.934) and volume of bitumen (11%). Figures 4.2 and 4.3 show the fatigue life using the isotropic and anisotropic material properties.

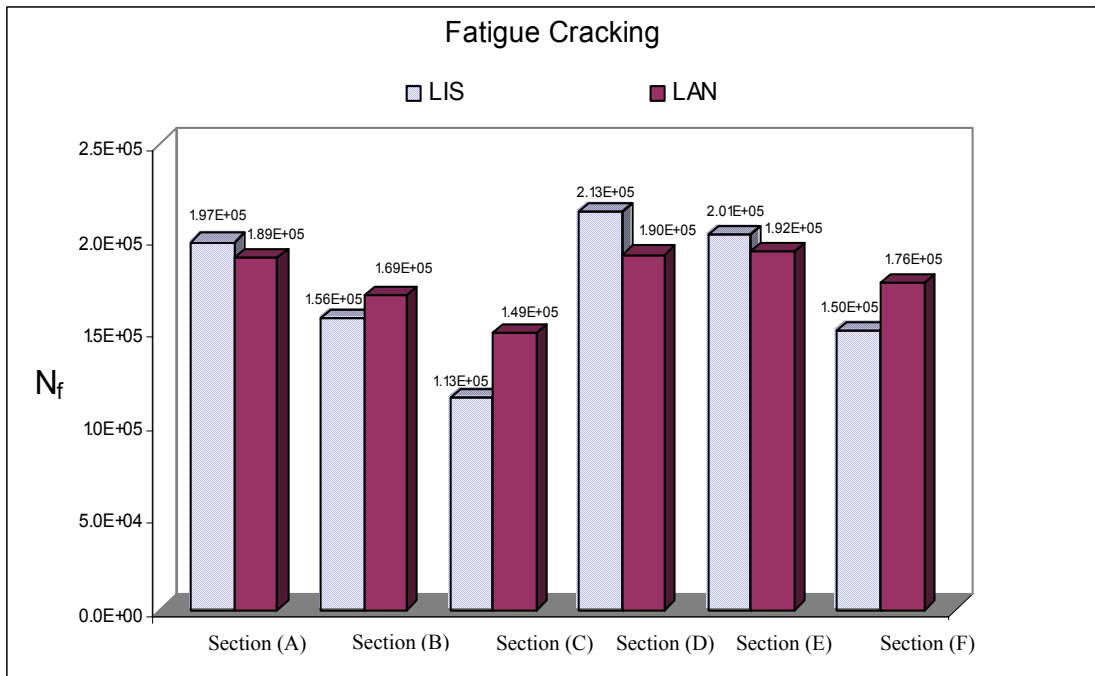

FIGURE 4.2 Comparison between linear isotropic and linear anisotropic models of the allowable number of load repetitions using the Shell method.

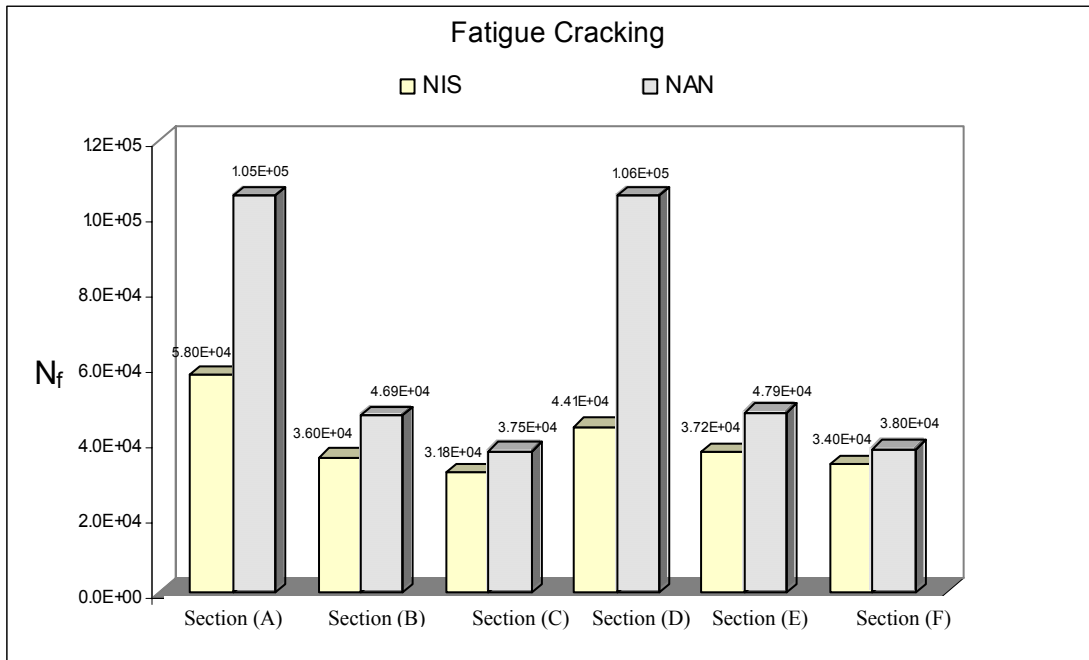

FIGURE 4.3 Comparison between non-linear isotropic and non-linear anisotropic models of the allowable number of load repetitions using the Shell method.

It can be seen from Figure 4.2 that the anisotropic model starts to give higher number of load repetitions than the isotropic models when the thickness of the HMA layer increases in the linear analysis. In the case of nonlinear analysis, it can be seen that the anisotropic model gives longer fatigue life than the isotropic model. These results can explain part of the shift factor between the laboratory fatigue life and the field fatigue life. It is clear that using anisotropic properties predicts longer fatigue life and less shift factor.

Figures 4.4 and 4.5 show a comparison between the linear isotropic and linear anisotropic models based on the tensile strain distribution across the depth of the asphalt and base layer. It can be seen from this figure that the tensile strain at the bottom of HMA for the isotropic model is more than that for the anisotropic model. Appendix A

includes the strain profiles for the sections in Figure 4.1 calculated using the different models in Table 4.1.

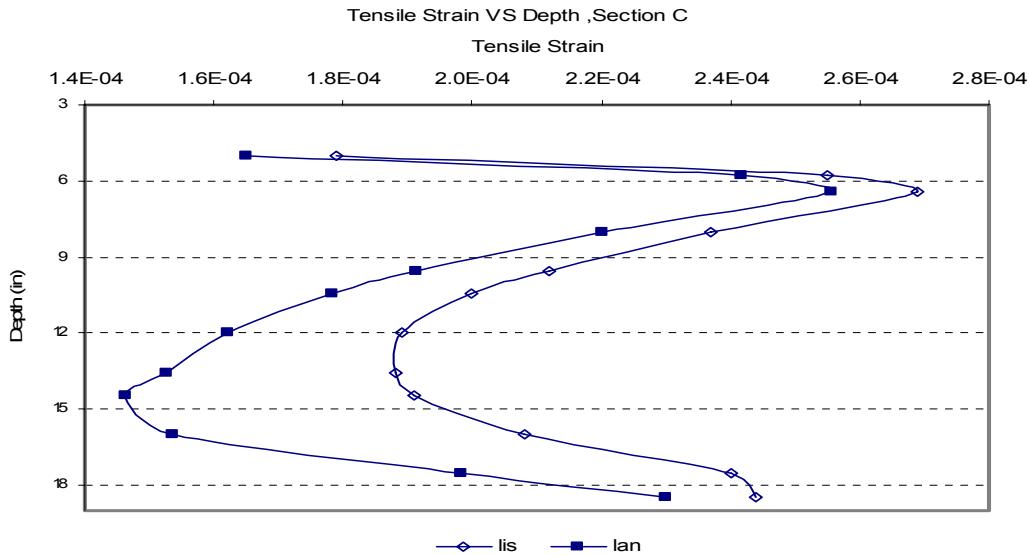

FIGURE 4.4 The tensile strain profiles in the asphalt and base layers of section C using linear isotropic and anisotropic properties.

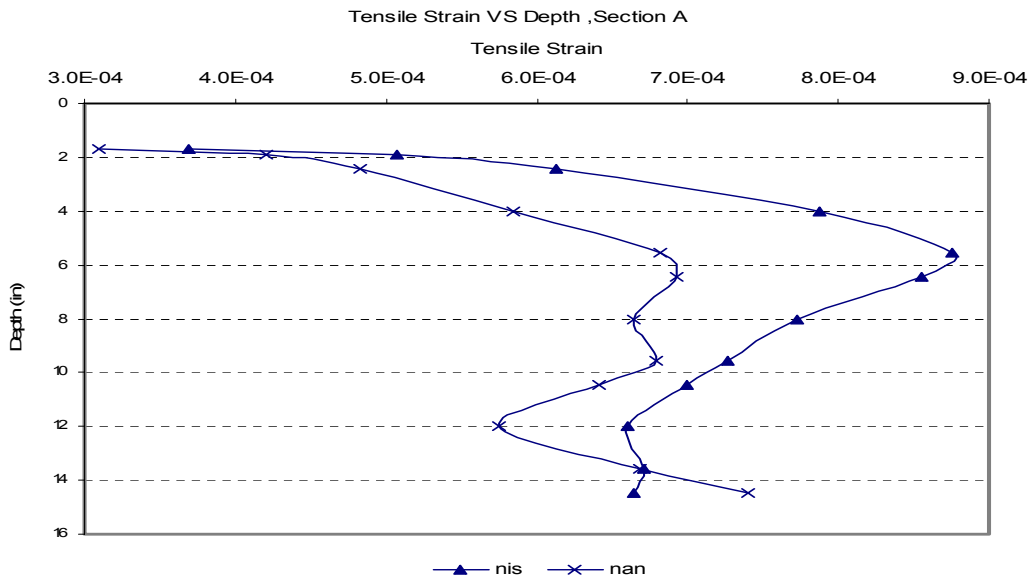

FIGURE 4.5 The tensile strain profiles in the asphalt and base layers of section A using nonlinear isotropic and anisotropic properties.

The Asphalt Institute equation (Eq.4.9) was also used to determine the fatigue life using a volume of bitumen of 11 % and percentage air voids in the asphalt mix equal to about 7.5%. Figure 4.6 and Figure 4.7 show comparisons in fatigue life using isotropic and anisotropic material properties. The results are in accordance with those from the Shell method. More specifically, the nonlinear anisotropic analysis predicts longer fatigue life than the nonlinear isotropic analysis.

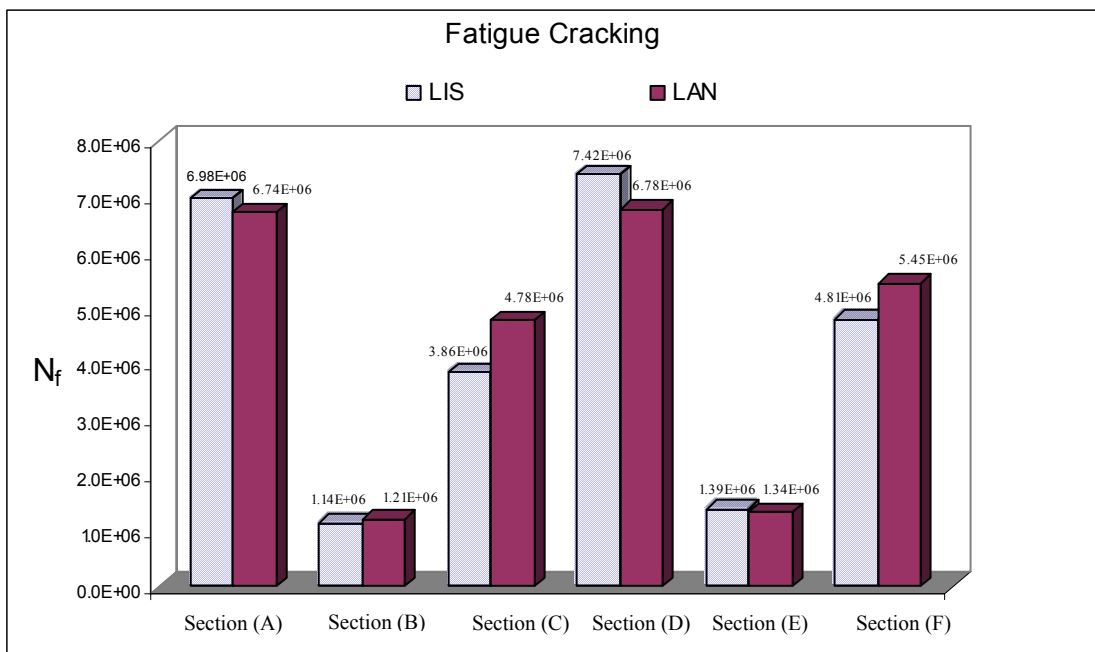

FIGURE 4.6 Comparison between linear isotropic and linear anisotropic models of the allowable number of load repetitions using the Asphalt Institute method.

FIGURE 4.7 Comparison between nonlinear isotropic and nonlinear anisotropic models of the allowable number of load repetitions using the Asphalt Institute method.

The fatigue life predicted by the Asphalt Institute model is much longer than that predicted by the Shell model. This is attributed to the fact that the Asphalt Institute method was calibrated with field data, while the Shell method was not. It is interesting to note that the results show that thin pavements can have longer fatigue life than the thick pavements. This is consistent with the findings by the AASHTO 2002 team that it is not necessary that the magnitude of tensile strain increases proportionally to a decrease in HMA thickness.

#### 4.4 Permanent Deformation Models in the AASHTO 2002 Guide

Permanent deformation is one of the most important distresses occurring in the flexible pavement. It is associated with rutting in the wheel path and develops gradually as the

number of load repetitions increase. For many years it was assumed that the permanent deformation is related to the vertical compressive strain at the top of subgrade so the rutting can be reduced by limiting the vertical compressive strain at the top of subgrade. The AASHTO 2002 considers the total permanent deformation in all layers in the pavement structure.

The Tseng and Lytton model is used to predict the permanent deformation in the asphalt, base and subgrade layers. The model has three parameters ( $\epsilon_0$ ,  $\beta$  and  $\rho$ ), and it describes the relationship between the permanent strains and the number of load repetitions (24). Many factors affect the permanent deformation of the pavement layers; stress state, density, moisture content, asphalt content, temperature, and other material and environmental characteristics. The three parameters in the asphalt layer are sensitive to resilient modulus, deviatoric stress, asphalt content and temperature, while the three parameters in the granular base material are functions of resilient modulus, confining pressure and the water content. In addition to the factors used in the equations for the granular materials, it was found that the deviatoric stress is also a significant factor which affects the values of the parameters in the subgrade soil. In the model, the three parameters are used as a fractional increase of total strains for each layer in the pavement.

In this study, the vertical resilient strains were calculated at the middle of each layer (or sublayer) using the finite element program. The permanent deformation is taken as the summation of the permanent deformations in all sublayers.

For a single axle load, the permanent Deformation,  $\delta_a$ , is given by

$$\delta_a(N) = \sum_{i=1}^n \left\{ \left( \frac{\varepsilon_{0i}}{\varepsilon_{ri}} \right) e^{-\left(\frac{\rho_i}{N}\right)^{\beta_i}} \int_{h_{i-1}}^{h_i} \varepsilon_v(Z) dz \right\} \quad (4.13)$$

where

$\delta_a$  = permanent deformation for layer/sublayer,

$\varepsilon_v$  = average vertical resilient strain in the layer/sublayer as obtained from the primary response model,

$h$  = thickness of the layer/sublayer,

$\varepsilon_r$  = resilient strain imposed in laboratory test to obtain material properties  $\varepsilon_0$ ,  $\rho$  and  $\beta$ ,

$\varepsilon_0$ ,  $\beta$  and  $\rho$  = material properties.

The equations of the three parameters are (some of the signs in these equations are modified here based on discussion with Dr.Lytton):

#### Asphalt Layer

$$\log \beta = -5.04349 + 0.01812A_c + 0.011045A_c^2 + 0.01127T - 0.203249 \log \sigma_d + 1.12228 \log E_r \quad (4.14)$$

$$\log \beta = -2.51475 + 0.60816A_c - 0.05282A_c^2 - 0.00214T + 0.16597 \log \sigma_d - 0.0000002E_r \quad (4.15)$$

$$\log \rho = 8.105675 - 4.241965 A_c + 0.54159 A_c^2 + 0.03865T - 0.01487 \sigma_d + 0.000005 E_r \quad (4.16)$$

#### Granular Material

$$\log \left( \frac{\varepsilon_0}{\varepsilon_r} \right) = 0.80978 - 0.06626W_c + 0.003077\sigma_\theta + 0.000003E_r \quad (4.17)$$

$$\log \beta = -0.919 + 0.03105W_c + 0.001806\sigma_\theta - 0.0000015E_r \quad (4.18)$$

$$\log \rho = -1.78667 + 1.45062W_c + 0.003784\sigma_\theta^2 - 0.002074W_c^2\sigma_\theta - 0.0000105E_r \quad (4.19)$$

### Subgrade

$$\log\left(\frac{\varepsilon_0}{\varepsilon_r}\right) = -1.69867 + 0.09121W_c - 0.11921\sigma_d + 0.91219\log E_r \quad (4.20)$$

$$\log \beta = -0.973 - 0.0000278W_c^2\sigma_d + 0.017165\sigma_d - 0.00000338W_c^2\sigma_\theta \quad (4.21)$$

$$\log \rho = 11.009 + 0.0000681W_c^2\sigma_d - 0.4026\sigma_d + 0.00000545W_c^2\sigma_\theta \quad (4.22)$$

where

$W_c$  = water content(%),

$\sigma_d$  = deviatoric stress (psi),

$\sigma_\theta$  = bulk stress (psi),

$E_r$  = resilient modulus of the layer/sublayer(psi).

The form of the Tseng and Lytton model was modified in the AASHTO 2002 to include a calibration factor:

$$\delta_a(N) = \beta_1 \left(\frac{\varepsilon_0}{\varepsilon_r}\right) e^{-\left(\frac{\rho}{N}\right)^\beta} \varepsilon_v h \quad (4.23)$$

where

$\beta_1$  = calibration factor for the unbound granular and subgrade materials; equal to 2.2 for the base layer while it is equal to 8.0 for the subgrade soil.

The equations used to get the three parameters  $\varepsilon_0$ ,  $\beta$  and  $\rho$  in the base and subgrade layers in the AASHTO 2002 are different than the ones proposed by Tseng and

Lytton. The stress term is eliminated from the equations in the AASHTO 2002. The relationships for the base and subgrade are as follows:

$$\log \beta = -0.61119 - 0.017638W_c \quad (4.24)$$

$$\log \left( \frac{\varepsilon_0}{\varepsilon_r} \right) = \frac{\left( e^{(\rho)^\beta} * a_1 E_r^{b_1} \right) + \left( e^{(\rho/10^7)^\beta} * a_7 E_r^{b_7} \right)}{2} \quad (4.25)$$

$$C_0 = \ln \left[ \frac{a_1 E_r^{b_1}}{a_7 E_r^{b_7}} \right] \quad (4.26)$$

$$\rho = 10^7 \left[ \frac{C_0}{\left( 1 - (10^7)^\beta \right)} \right]^{\frac{1}{\beta}} \quad (4.27)$$

$$W_c = 51.712 \left[ \left( \frac{E_r}{2555} \right)^{\frac{1}{0.64}} \right]^{-0.3586 * GWT^{0.1192}} \quad (4.28)$$

Where:

$W_c$  = water content (%),

$E_r$  = resilient Modulus of the layer/sublayer (psi),

GWT = ground water table depth (ft),

$a_1$  = 1.0942e-18,

$b_1$  = 3.520049,

$a_7$  = 0.03162278,

$b_7$  = 0.5.

The relationship used in the AASHTO 2002 to predict the permanent deformation in the Asphalt layer is based on the statistical analysis of laboratory repeated load permanent deformation tests.

The final equation conducted by Leahy, Ayers and Kaloush to predict the permanent deformation is as follows:

$$\frac{\varepsilon_p}{\varepsilon_r} = K_1 * 10^{-3.51108} N^{0.479244} T^{1.5606} \quad (4.29)$$

$$C_1 = -0.1039 * H_{ac}^2 + 2.4868 * H_{ac} - 17.342 \quad (4.30)$$

$$C_2 = 0.0172 * H_{ac}^2 - 1.7331 * H_{ac} + 27.428 \quad (4.31)$$

where

$\varepsilon_r$  = the vertical resilient strain at any depth (obtained from the primary response model),

N = allowable number of load repetitions,

T = temperature (F),

$\varepsilon_p$  = plastic strain,

$k_1$  = function of total asphalt layer thickness and depth to computational point, to correct for the confining pressure at different depths.

The rut depth for each sublayer in the AC layer can be found from

$$\Delta R_{di} = \varepsilon_{pi} \Delta h_i \quad (4.32)$$

The summation for all incremental  $\Delta R_d$ , the total layer rut depth can be obtained from

$$R_d = \sum_{i=1} \Delta R_{di} \quad (4.33)$$

#### 4.5 Analysis of Permanent Deformation Using Isotropic and Anisotropic Models

It was found that the permanent strain calculated using anisotropic properties is higher than that using isotropic properties in the asphalt layer. An example of the results is shown in Figure 4.8. This is attributed to the higher compressive strain in the anisotropic model compared with the isotropic model, although the deviatoric stress is less for the anisotropic model. Examples of the results are shown in Figures 4.9 and 4.10. The results for the other sections are given in Appendix A

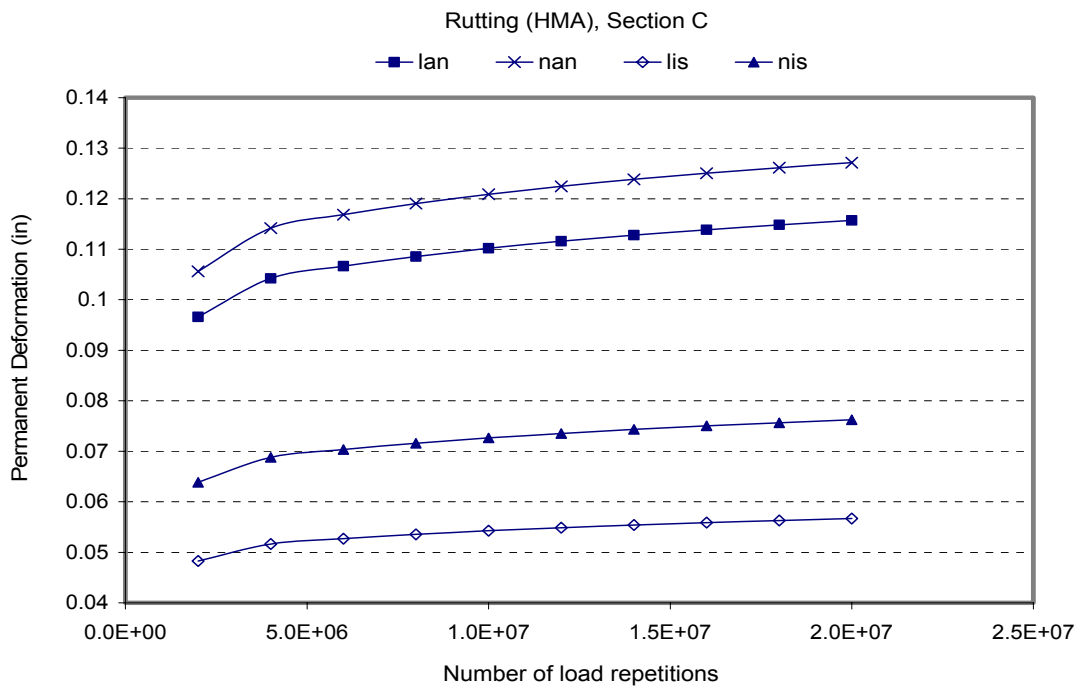

FIGURE 4.8 HMA permanent deformation in section C using the Tseng and Lytton model.

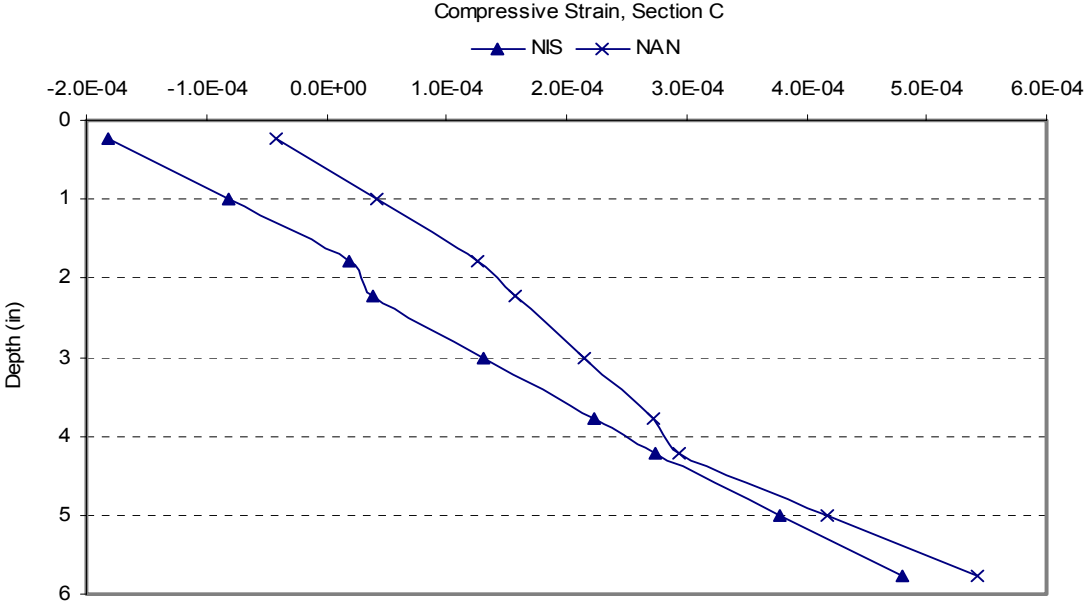

FIGURE 4.9 The compressive strain profiles in the asphalt layer of section C using non-linear isotropic and anisotropic properties.

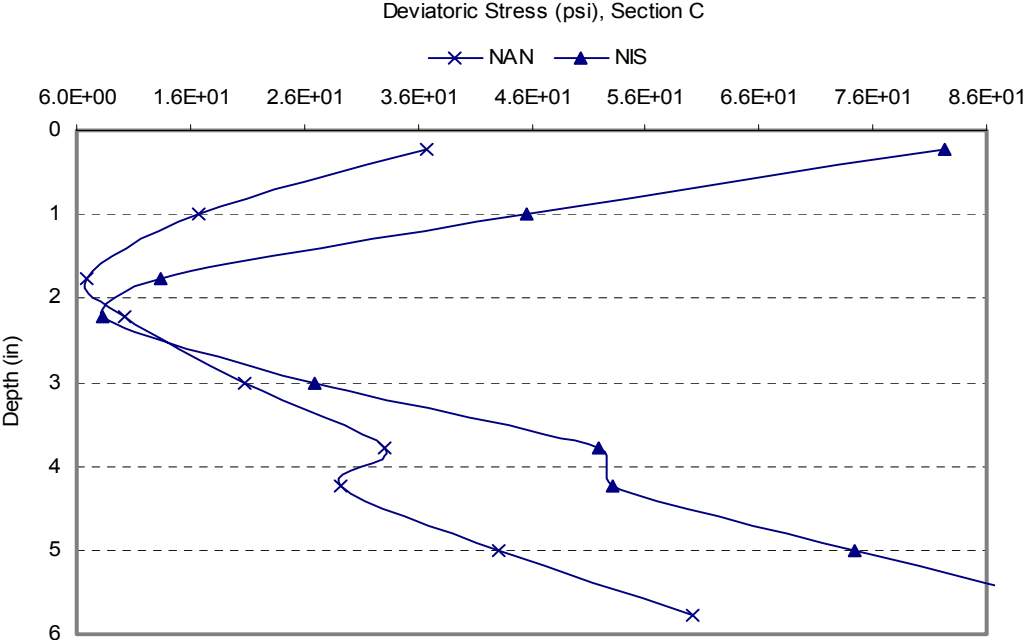

FIGURE 4.10 The deviatoric stress profiles in the asphalt layer of section C using non-linear isotropic and anisotropic properties.

Figure 4.11 shows that the permanent deformation in the base layer obtained by using anisotropic properties is always more than the isotropic model. This is caused by the higher compressive strain in the base layer for the case of using anisotropic properties (Figure 4.12). It should be noticed that the bulk stress is higher for the anisotropic model (Figure 4.13). The results indicate that the compressive strain rather than the bulk stresses is more dominant the design in terms of permanent deformation. The results for the other sections are shown in Appendix A.

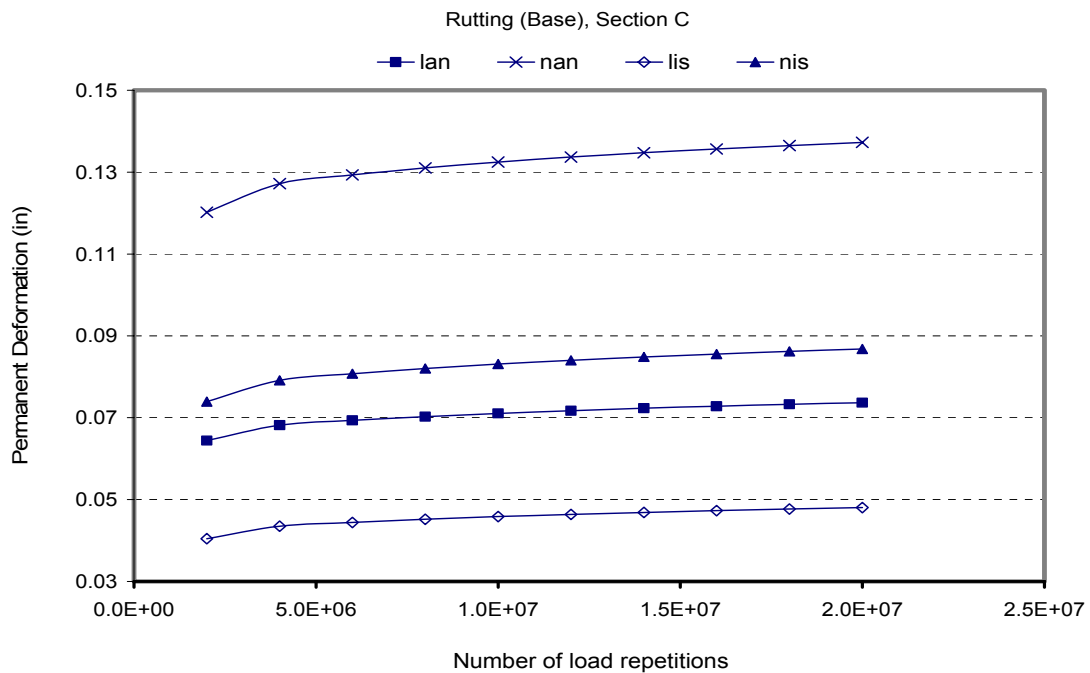

FIGURE 4.11 Permanent deformation in the base of section C using the Tseng and Lytton model.

FIGURE 4.12 Compressive strain profiles in the base layer of section C using non-linear isotropic and anisotropic properties.

FIGURE 4.13 The bulk stress profiles in the base layer of section C using non-linear isotropic and anisotropic properties.

FIGURE 4.14 The deviatoric stress profiles in the base layer of section C using non-linear isotropic and anisotropic properties.

The bulk stress at the top of subgrade is higher for the anisotropic model as can be seen from Figure 4.13. The deviatoric stress (Figure 4.14) and the vertical compressive strain for the anisotropic model can be higher or lower than those of the isotropic. However, the resultant of the effects of the bulk stress, deviatoric stress and the vertical strain give less permanent deformation using the anisotropic properties (Figure 4.15).

Figure 4.16 shows the total rutting in section C. The results show that the permanent deformation for the nonlinear isotropic model is more than that for the nonlinear anisotropic model.

FIGURE 4.15 Subgrade permanent deformation in section C using the Tseng and Lytton model.

FIGURE 4.16 Total permanent deformation in section C using the Tseng and Lytton model.

The permanent deformation was also calculated in the pavement layers using the regression equations implemented in the AASHTO 2002 guide. The permanent deformation for the anisotropic model is more than that for the isotropic model (Figure 4.17).

FIGURE 4.17 HMA permanent deformation in section C using the AASHTO 2002 model.

It can be seen from Figure 4.18 that the permanent deformation in the base layer obtained using the anisotropic model is always more than the isotropic model. For the subgrade, the permanent deformation obtained by using isotropic model can be more or less than that calculated using the anisotropic model depending on the section and the material properties. An example of the subgrade permanent deformation is in Figure

4.19. Figure 4.20 shows that the total rutting for the anisotropic model is always more than that for isotropic model.

#### 4.6 Summary of Findings

In this chapter the permanent deformation and fatigue cracking were calculated based on the mechanistic-empirical models used in AASHTO 2002 with isotropic and anisotropic material properties. The following points summarize the results:

- For the base and Asphalt layer, the permanent deformation obtained using the anisotropic model is always more than that with the isotropic model.
- The permanent deformation in the subgrade obtained using the isotropic model is more than that for the anisotropic model when the regression equations from Tseng and Lytton are used. However, the permanent deformation using the isotropic model can be more or less than that calculated using the anisotropic model when the regression equations used in the AASHTO 2002 are used.
- The total permanent deformation using the isotropic model can be more or less than that for anisotropic model when the regression equations from Tseng and Lytton are used. However, the total permanent deformation using the anisotropic model is more than that calculated using the isotropic model when the AASHTO 2002 equations are used.
- The fatigue life predicted using the nonlinear anisotropic approach is higher than the life predicted using the nonlinear isotropic approach. This can explain part of the high shift factor typically found between the laboratory fatigue life calculated using the isotropic analysis, and field fatigue life. This shift factor is reduced when anisotropic properties are used.

## CHAPTER V

### SENSITIVITY ANALYSIS OF THE AASHTO 2002 DESIGN GUIDE

#### 5.1 Introduction

This chapter documents the results of the sensitivity analysis of the AASHTO 2002 design guide to the characteristics of the materials used in the unbound pavement layers. The sensitivity analysis includes two asphalt binder grades, two asphalt layer thicknesses, three thicknesses for the base layer, five stiffness moduli for the base layer, three stiffness moduli for the subgrade layer, and three geographic locations representing different environmental conditions.

#### 5.2 Background on the AASHTO 2002 Design Guide

The previous AASHTO guide for the design of pavement for both flexible and rigid pavement was developed based on the AASHO road test experiment about 35 years ago.

There are several limitations of this design procedure such as (6):

- 1) Pavement rehabilitation design procedures did not exist at the AASHO road test.
- 2) The AASHTO road test did not take into accounts the effects of differences in the climate.
- 3) One type of subgrade was used.
- 4) There is a big difference between the traffic used in 1950 and the traffic in modern pavements.
- 5) Aging was not addressed because the duration of the road test was just 2 years.

The 2002 design guide is developed based on the mechanistic empirical design approach that accounts for the climate, aging, and modern vehicle loading. Analysis of the sensitivity of the AASHTO 2002 flexible pavement design procedure design to the base properties is presented in this chapter. The material properties used in the analysis are discussed in the following sections.

### **5.3 Input for the Sensitivity Analysis**

Three traffic levels are used in the analysis based on the default values in the AASHTO 2002 guide. The traffic parameters are as follows:

- Two way average annual daily truck traffic = 1500, 3000, 5000
- Number of lanes in the design direction = 2
- Percent of trucks in design direction = 50%
- Percent of trucks in design lane = 95%
- Optional speed limit = 55 mph
- Design life = 10 years
- Traffic growth = 4%

The environmental conditions have a significant effect on the performance of the flexible pavement. There are two methods to generate the climatic data in the AASHTO 2002 software. The first method is by using the data available in the software since the design guide software includes a database for over 400 cities in the U.S. The next method is by providing the following inputs: pavement location latitude and longitude and the elevation besides the water table depth. Then the climatic data are interpolated

to the actual project location. In this analysis, three locations were selected to represent different climatic regions: Houston-Texas, Pullman-Washington State, and New York City. Table 5.1 summarizes all the variables used in the sensitivity analysis. The results presented in this chapter are from the analysis of the Texas site. The results from the other two sites followed the same trends and, their results are included in Appendix C.

Different pavement sections were analyzed to represent a wide spectrum of structural designs. The material properties used for the different layers are shown in Tables 5.2 and 5.3.

#### 5.4 Analysis and Results

The sensitivity analysis was conducted based on the main distresses which may occur in the pavement. The main distresses include roughness, rutting, and fatigue cracking (top down and bottom up cracking). All figures are presented as the percent change in a certain distress as a function of change in the base material type and thickness with respect to reference values. The results are shown in Tables 5.4- 5.15.

### 5.4.1 Roughness

Smoothness can be defined as “the variation in surface elevation that induces vibrations in traversing vehicles” (6). Rough roads not only lead to user discomfort but also to increased travel times and higher vehicle operating costs. The IRI is one of the ways to measure the smoothness. The designer has to choose the terminal IRI values that should not be exceeded at the design level of reliability. Typical values range from 63 to 1260 in/mi (6). Figure 5.1 shows the change in the IRI as the base modulus changes from 42,000 psi to 28,000 psi for different thicknesses for the base layer. The y axis represents the percentage change in the IRI as the base modulus changes from 42,000 psi to another value where the data point is plotted. It can be seen that the IRI value increases as the base modulus gets smaller irrespective of the base thickness. As can be seen in Figure 5.2, the effect of the change in the base modulus on IRI becomes smaller as the HMA thickness becomes larger. The influence of base thickness on IRI increases as the HMA thickness decreases and as the subgrade stiffness decreases, (Figure 5.3). These results are almost the same for PG 58-22 and PG 72-22 mixes.

FIGURE 5.1 Percent change in IRI for different thicknesses of the base layer at 8in HMA and 8 ksi subgrade.

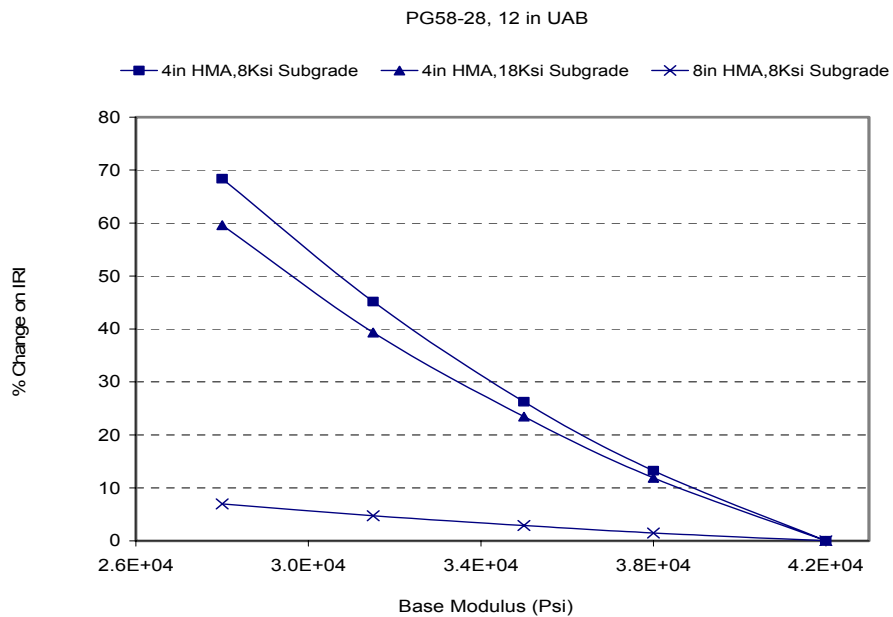

FIGURE 5.2 Percent change in IRI at two different thicknesses of HMA and at two types of subgrade by changing the base modulus.

FIGURE 5.3 Percent change in IRI at two different thicknesses of HMA and at two types of subgrade by changing the base thickness.

#### 5.4.2 Surface-Down Fatigue Cracking (Longitudinal Cracking)

Surface down fatigue cracking is defined as longitudinal cracking at the edge of the wheel paths. Surface-down cracking can cause loss of smoothness and permits water infiltration into the underlying pavement layers which can be a reason for structural failure of the pavement. The performance criterion for surface down fatigue cracking is defined as the maximum allowable length of longitudinal cracking per mile of pavement that is permitted to occur at the end of the design life. Typical values of allowable surface down fatigue cracking are on the order of 500 to 2000 ft/mi of pavement (6). The longitudinal cracking is calculated by considering the critical tensile stress at the surface and at 0.5 inch below the surface.

The base type has significant influence on longitudinal cracking as shown in Figure 5.4. Longitudinal cracking increases up to 190% when the base modulus decreases from 42,000 psi to 28,000 psi in a pavement with PG 58-28 binder, 8000 psi subgrade, and 15in base thickness. The influence of base modulus on longitudinal cracking decreases as the base thickness decreases (Figure 5.4), and as the HMA thickness increases (Figures 5.4 and 5.5). Also, comparing Figures 5.4 and 5.5 with Figures 5.6-5.8 reveals that the influence of the base modulus on fatigue cracking decreases as the subgrade modulus increases. Figures 5.9 – 5.11 show clearly that the longitudinal cracking increases as the base thickness decreases. The relationship between base thickness and longitudinal cracking is sensitive to subgrade stiffness and HMA thickness as shown in Figures 5.9-5.12.

FIGURE 5.4 Percent change in longitudinal cracking for different thickness of the base layer at 4 in HMA and 8 ksi subgrade.

FIGURE 5.5 Percent change in longitudinal cracking for different thickness of the base layer at 8 in HMA and 8 ksi subgrade.

FIGURE 5.12 Percent change in longitudinal cracking for different types of the base layer at 8 in HMA and 18 ksi subgrade.

### 5.4.3 Bottom-Up Fatigue Cracking

This type of cracking starts from the bottom of the layer and propagates to the top so the critical fatigue depth location is at the bottom of the asphalt layer. Bottom-up fatigue cracking appears as alligator cracking within the wheel paths (6). Bottom-up cracking has an effect on the smoothness which can cause loss of smoothness and can permit water infiltration into the underlying pavement layers that can cause structural failure of the pavement. The performance criterion for bottom-up fatigue cracking is defined as the percentage of the cracking per total lane area that may occur over the design period. Typical values of allowable surface down fatigue cracking are on the order of 25 to 100% of pavement (6). The alligator cracking is calculated by considering the critical tensile stress at the bottom of the pavement.

The base type has significant influence on alligator cracking as shown in Figure 5.13. Alligator cracking increases by about 50% when the base modulus decreases from 42,000 psi to 28,000 psi in a pavement with PG 58-28 binder, 8000 psi subgrade, and 15in base thickness. The influence of base modulus on alligator cracking decreases as the base thickness decreases (Figure 5.13) and as the HMA thickness decreases (Figures 5.13 and 5.14). Also, comparing Figures 5.13 and 5.14 with Figures 5.15 and 5.16 indicates that the influence of the base modulus on fatigue cracking is the same irrespective of the subgrade type. Figures 5.17 and 5.20 show clearly that the base thickness has significant influence on alligator cracking. The relationship between base thickness and alligator cracking depends on subgrade stiffness and HMA thickness as shown in Figures 5.17-5.20.

FIGURE 5.13 Percent change in alligator cracking for different thicknesses of the base layer at 8 in HMA and 8 ksi subgrade.

FIGURE 5.20 Percent change in alligator cracking for different types of the base layer at 8 in HMA and 18 ksi subgrade.

#### 5.4.4 Permanent Deformation

Permanent deformation is one of the most important types of distresses in flexible pavements. Water can accumulate in traffic lanes and reduce skid resistance of the surface and cause unsafe traffic conditions. In AASHTO 2002 Design guide, the permanent deformation is calculated at the middepth of each sublayer within the pavement so the overall permanent deformation is the summation of the permanent deformation for all the layers. The performance criterion for total permanent deformation is defined in terms of the maximum rut depth in the wheel path. A typical maximum rut depth for total permanent deformation is about 3 in (6).

All the results from the permanent deformation analysis show that the base properties have almost no influence on permanent deformation (Figures 5.21-5.26). This is a surprising result given that the main function of the base layer is the distribution of applied loads to reduce permanent deformation. The analysis in chapter IV of this thesis showed that the permanent deformation models are sensitive to the base properties. This indicates that the implementation of these models in the AASHTO 2002 should be carefully reviewed.

FIGURE 5.21 Percent change in rutting for different thicknesses of the base layer at 4 in HMA and 8 ksi subgrade.

FIGURE 5.26 Percent change on rutting for different types of the base layer at 4 in HMA and 18 ksi subgrade.

## **5.5 Summary of Findings**

The sensitivity analysis results show that the base modulus and thickness have significant influence on the international roughness index and the longitudinal cracking. The influence of base properties on alligator cracking is about half of the influence of base properties on longitudinal cracking. All the results show that the base properties have almost no influence on permanent deformation. These findings are applicable to the three climatic zones, the two asphalt binder grades, and three traffic levels used in this study.

## CHAPTER VI

### CONCLUSIONS

It is evident from the literature that there is a need to compare the calculated response of isotropic and anisotropic pavement models based on field experimental sections. This was achieved in this thesis by comparing the models predictions with the AASHO deflection measurements. The analysis included sections with different profiles and materials properties. Anisotropy was modeled by the ratio of the horizontal modulus to vertical modulus. The percentage of error between predictions and measurements decreased as the anisotropy increased. The predictions correlated the best with the experimental measurements when the horizontal modulus was about 30% of the vertical modulus. The predictions matched the AASHO measurements in the fall season better than the measurements in the spring season. As reported in the AASHO experiment, distresses were detected in the spring season that might have caused the response to deviate from the elastic solutions used in the FEM.

A critical review was conducted for the models used in the AASHTO 2002 design guide. The review focused on the differences between these models and the original models on which the AASHTO 2002 models were developed. It was found that the original models (Asphalt Institute Shell model for fatigue and Tseng and Lytton model for permanent deformation) were modified based on calibration with field data mainly from the LTPP database. The predictions from the original models can differ from the predictions of the AASHTO 2002 models.

The permanent deformation and fatigue cracking were calculated based on the mechanistic-empirical models used in AASHTO 2002 using isotropic and anisotropic material properties. The permanent deformation in the asphalt and base layers obtained using the anisotropic model is always more than that from the isotropic model. The permanent deformation in the subgrade obtained using the isotropic model is more than that for the anisotropic model when the regression equations from Tseng and Lytton are used. However, the permanent deformation using the isotropic model can be more or less than that calculated using the anisotropic model when the regression equations used in the AASHTO 2002 are used. The total permanent deformation using the isotropic model can be more or less than that for the anisotropic model when the regression equations from Tseng and Lytton are used. However, the total permanent deformation using the anisotropic model is more than that calculated using the isotropic model when the AASHTO 2002 equations are used.

The fatigue life predicted using the nonlinear anisotropic approach is higher than the life predicted using the nonlinear isotropic approach. This can explain the high shift factor typically found between the laboratory fatigue life calculated using the isotropic analysis, and the field fatigue life. This shift factor can be reduced when anisotropic properties are used.

The sensitivity analysis of the AASHTO 2002 model shows that the base modulus and thickness have significant influence on the international roughness index and the longitudinal cracking. The influence of base properties on alligator cracking is about half of the influence of base properties on longitudinal cracking. Surprisingly, all

the results show that the base properties have almost no influence on permanent deformation. These findings are applicable to all the material properties, pavement profiles, and environmental conditions used in this study. The implementation of the AASHTO 2002 guide to the permanent deformation model should be carefully reviewed to address this discrepancy.

## VITA

Sanaa Ahmad Masad was born in Kuwait on January 20, 1978. She received her Bachelor of Science in Civil Engineering from Jordan University of Science and Technology in June 2001. She worked as an engineer for Al-Zoabe Construction Company in Irbid, Jordan from August of 2001 to August of 2002. She started her Master of Science program in civil engineering at Washington State University in August 2002 and transferred to Texas A&M University in January 2003. Her permanent address is:

Sanaa Masad

Irbid-Jordan

Tel: 02 7 250 129
