ABSTRACT<br>Relative Damaging Ability of Galactic Cosmic Rays Determined Using Monte Carlo<br>Simulations of Track Structure. (August 2011)<br>Bradley William Cox, B.S., University of Texas<br>Co-Chairs of Advisory Committee: Dr. Leslie A. Braby<br>Dr. Stephen Guetersloh

The energy deposition characteristics of heavy ions vary substantially compared to those of photons. Many radiation biology studies have compared the damaging effects of different types of radiation to establish relative biological effectiveness among them. These studies are dependent on cell type, biological endpoint, radiation type, dose, and dose rate. The radiation field found in space is much more complicated than that simulated in most experiments, both from a point of dose-rate as well as the highly mixed field of radiative particles encompassing a broad spectrum of energies. To establish better estimates for radiation risks on long-term, deep space missions, the damaging ability of heavy ions requires further understanding. Track structure studies provide significant details about the spatial distribution of energy deposition events in and around the sensitive targets of a mammalian cell. The damage imparted by one heavy ion relative to another can be established by modeling the track structures of ions that make up the galactic cosmic ray (GCR) spectrum and emphasizing biologically relevant target geometries.

This research was undertaken to provide a better understanding of the damaging ability of GCR at the cellular level. By comparing ions with equal stopping power values, the differences in track structure will illuminate variations in cell particle traversals and ionization density within cell nuclei. For a cellular target, increased particle traversals, along with increased ionization density, are key identifiers for increased damaging ability.

Performing Monte Carlo simulations with the computer code, FLUKA, this research will provide cellular dosimetry data and detail the track structure of the ions. As shown in radiobiology studies, increased ionizations within a cell nucleus generally lead to increased DNA breaks and increased free radical production, resulting in increased carcinogenesis and cell death. The spatial distribution of dose surrounding ions' tracks are compared for inter- and intracellular regions. A comparison can be made for many different ions based upon dose and particle fluence across those different regions to predict relative damaging ability. This information can be used to improve estimates for radiation quality and dose equivalent from the space radiation environment.

## DEDICATION

This dissertation is dedicated to my family and friends for their unwavering support during the last four years of my graduate program. Thank you for helping to make this a wonderful experience for me.

## ACKNOWLEDGEMENTS

I would like to thank the U.S. Department of Veterans Affairs for the continual financial support over my entire four years in graduate school.

I would like to thank the National Space Biomedical Research Institute's Space Life Sciences program for financial support and for introducing me into the space radiation biology community. The internship at Johnson Space Center and NASA Space Radiation Summer School were invaluable experiences.

Finally, I would like to thank my advisory committee for their guidance and the knowledge they've passed on to me.

## CHAPTER I

## INTRODUCTION

Galactic cosmic rays (GCR) pose a substantial health risk to astronauts in space. The primary risk of interest in space radiation biology studies is an increased chance of cancer induction later in life. Uncertainties in risk estimates, caused by the interaction of GCR in human tissue, stem primarily from uncertainties in radiation quality factors (NCRP 2006). Dose equivalent, calculated using a quality factor, is not specific enough to predict the differences in damaging ability of the components of the GCR spectrum. The ICRP notes the uncertainties involved by emphasizing that the quality factor and individual tissue weighting factors are designed for general radiation protection practices and serve only as rough indicators of risk, not actual risk assessment (ICRP 2003). The generally accepted methods for determining quality factor do not account for differences in particle tracks of different ions with equal linear energy transfer (LET). The LET can be equal for different particle species with different velocities, but radiobiological studies often indicate differing levels of damaging ability.

This research is designed to provide better estimates for the biological risks of GCR by improving the knowledge of the energy deposited in cell nuclei by GCR particle tracks. The damaging ability of an ion will be established relative to that of other ions of the GCR spectrum by comparing their particle tracks in a water medium.

This dissertation follows the style of Health Physics.

Variations in the particle trajectories of different ions cause a change in the spatial distribution of energy depositions in a target. Transport modeling that accounts for all processes along the path of the ion, rather than electromagnetic energy loss alone, will be used. This is performed by computational modeling using FLUKA. This Monte Carlo simulation approach details specific energy deposition events, while well-accepted theoretical methods, including amorphous track modeling, are used as a baseline for overall comparison. Detailed study of individual events is necessary because target effects are based on the spatial distribution of energy deposition events relevant to strand breaks and clustering instead of overall averaging. The effects of different ions can be compared as a function of atomic number $(\mathrm{Z})$ and kinetic energy $\left(\mathrm{MeV} \mathrm{n}^{-1}\right)$. This research takes two approaches:

1. Compare the track structure of different ions having equal stopping power, and
2. Compare the track structure of different ions having equal velocity.

In the first case, ions have different velocities but lose energy at the same rate when traversing a thin target. In this case, variations in track structure are due to the spatial distribution of energy imparted in small volumes within the total volume and are largely a function of primary particle velocities. The ions with higher velocity produce higher-energy secondary electrons that travel farther from the primary track. They affect a much larger number of targets via secondary electron tracks. The ions with lower velocity affect fewer targets but deposit higher dose near the center of the track.

For the second case, spatial distributions of energy imparted in small volumes will be similar because the knock-on collision process will produce a spectrum of delta rays with similar kinetic energy spectra. In this case, the number of delta rays produced will be less for lower Z ions, meaning the total energy deposited is also less. It is the goal of this project to determine how these variations in energy deposition will affect targets on the cellular scale.

## CHAPTER II

## BACKGROUND

## Space Radiation Environment

Radiation dose received by astronauts on missions to space is a major topic of concern for planning future missions. During low-Earth orbit (LEO) missions, such as those conducted on the International Space Station (ISS) and Space Transport Shuttles, crews are exposed to GCR, solar particle events (SPE), and the protons and electrons that make up the Van Allen belts. The Earth's magnetosphere provides a high level of shielding from GCR and SPE by deflecting and fragmenting ions, offering some protection for astronauts in LEO. As one travels away from the Earth, radiation levels increase as the atmosphere and magnetosphere dissipate. Were a mission to travel beyond LEO, GCR and SPE become a greater concern, due to higher abundance of these particles. Dose rates are estimated to increase by a factor of two for deep space missions compared to LEO missions (NCRP 2006). As humankind looks to extend missions deeper into space, such as a manned mission to Mars, radiation levels become a significant concern for health risks. GCR and SPE are the focal point for radiationinduced cancer and risk estimates must be improved. To properly estimate radiation risk, detailed knowledge of the composition and energy spectra of GCR must be understood. Risk estimates currently in use are described in NCRP Report 132 (NCRP 2000) and pertain only to LEO. NCRP Report 153, Information needed to make
$\underline{\text { radiation protection recommendations for space missions beyond low-earth orbit (NCRP }}$ 2006), is intended to provide further guidance to include long term, deep space missions.

The GCR spectrum consists of heavy ions with a broad range of kinetic energy and penetrating ability. These ions traverse the spacecraft and human body, creating a complicated field of secondary radiations. Radiation dose received from GCR is associated with a large uncertainty, due to complicated interactions in target and shielding materials. Resulting biological effects from these complicated particle tracks pose additional uncertainties. Radiation shielding is mostly provided by the aluminum hull of the spacecraft, and its shallow thickness serves only to reduce the low-energy particle fluence. Mission cost is highly dependent on the amount of mass that is needed to be put into space. As a result, the amount of radiation shielding required to eliminate radiation exposure surpasses what is reasonably achievable for a mission. Rather than relying completely on shielding, improving radiation dose assessment techniques should prove to be an effective method for improving dose-risk assessment.

The GCR spectrum consists of many different charged particles, from protons to uranium, with energies from $10 \mathrm{MeV} \mathrm{n}^{-1}$ to $10^{12} \mathrm{MeV} \mathrm{n}^{-1}$ (NCRP 2006). Their abundances peak with kinetic energies of $300-700 \mathrm{MeV} \mathrm{n}^{-1}$, and ions heavier than iron are of such low abundance that they are usually ignored for personnel dosimetry. Particle fluence and kinetic energy are important in determining radiation dose, and Table 1 provides a relation across the GCR spectrum.

Table 1. Relative GCR abundance at several kinetic energies. Ion abundance is presented relative to $\mathrm{Si}-28$ which is set arbitrarily to 1000 (NCRP 2006). Ions shaded in blue are the object of study in this research.

The radiations of interest in this research are the GCR that present a mostly constant exposure of charged particles, making up a spectrum comprised mainly of
protons (87\%), helium (12\%), and HZE particles (1\%) (Ballarini et al. 2008). To specifically study the effects of track structure of these ions, those highlighted in blue in Table 1 were chosen for an in-depth dosimetry analysis. The relative abundance of different ions and energies varies as the solar activity modulates the GCR field. The solar wind blows radially outward, and at its maximum, creates a GCR minimum. It is more effective in reducing the fluence of the lower-energy GCR, which are also of higher abundance. The solar cycle lasts, on average, about 11 years (Cucinotta et al. 2001).

Solar particle events are a second source of radiation risk for long-term deep space missions. Although SPE that are strong enough to present a serious risk are very unlikely; increasing mission duration increases the chance of experiencing one. The ion spectrum of an SPE consists primarily of protons and to a lesser extent, helium. There is a small portion of higher Z ions associated with most events, but these are of such small abundance compared to GCR that they have little impact on radiation dose. The vast majority of protons and helium ions are low enough in energy that they are stopped by the walls of the spacecraft before they reach an astronaut inside the ship. Risks pertain to an astronaut working outside the ship on extravehicular activity or on the surface of the Moon. Much of the work going into protection from SPE lies in prediction capabilities. If these events can be predicted with adequate short warning, the astronaut may have enough forewarning to plan to return to shelter before the SPE arrives. Due to the rigorous work schedule on most missions, forecasting the conclusion of SPE is also
valuable, because it allows crewmembers advanced notice of when they would be able to return to work outside the spacecraft or shelter.

General radiation-protection practices utilize the factors of time, distance, and shielding to reduce radiation dose from external sources. Concerning GCR, exposure time is dependent on the mission, distance is not applicable, and the amount of shielding that can be carried to space is too minimal to significantly reduce the dose. To make accurate risk estimates, knowledge of the radiation field must be well understood. Effects due to GCR over long-term, deep space missions, are accompanied by a large source of uncertainty due to the interaction of the heavy ions with the spacecraft and other materials that significantly change and complicate the radiation spectrum. To analyze the impact of space radiation on a biological system, it is necessary to create models of the interactions of the radiation with shielding and target materials. Heavy ions with considerable kinetic energy create secondary particles from interactions while traversing a medium. Secondary radiations consist largely of photons, electrons, neutrons, and positively charged ion fragments that complicate a dose equivalent calculation. Fragments tend to retain a velocity similar to their parent giving them a much lower stopping power and a longer range. Target atoms can fragment as well, and these ions generally have very low velocity, very high stopping power, and very short range. The location of the astronaut, in conjunction with the variations in spacecraft walls and objects within the vessel impose additional difficulties in determining a realistic radiation field incident on an astronaut. The result is a radiation field inside the spacecraft that is quite different from the one outside it. Fragmentation of GCR leads to
a broader spread of secondary particles that will interact with more targets. These secondaries will have decreased cumulative stopping power but may interact with more cells in the human body, increasing risks. Secondary fragments also have longer ranges, reducing shielding effectiveness.

As these particles traverse cell nuclei only sporadically and generally with intervals between hits of a day or longer, averaged values are meaningless (Curtis et al. 1995). Focusing on the heavier ions, cells will only receive one particle traversal every few weeks. This significantly changes the energy deposition patterns concerning LET and relative biological effectiveness (RBE). The occasional heavy ion traversal experienced by a cell is significant because the RBE of heavy ions is generally greater than 1. These values will be discussed in depth in the next section. The GCR included in this research were chosen based on the measured relative abundance and provides a broad range of atomic numbers and kinetic energies. These particles interact with spacecraft materials and the human body to create a much more complicated radiation environment, producing nearly all radiative particles through electromagnetic and nuclear interactions.

NASA policy specifies the maximum allowable risk, caused by GCR related health effects, as a 3 percent increase in developing a fatal cancer due to radiation exposure on a space mission. The risk is established by combining dose and dose-rate estimates with radiation quality. A crewmember on ISS typically receives from $0.5-1.2$ $\mathrm{mSv} \mathrm{day}^{-1}$ (NCRP 2006). Approximately $75 \%$ is from GCR and $25 \%$ from protons encountered in passages through the South Atlantic Anomaly regions of the Van Allan
belts. When a mission leaves the Earth's magnetosphere, the dose is expected to roughly double, with a larger portion coming from heavy ions. For a six-month transit to Mars, effective doses as large as 1 Sv have been estimated from GCR. Absorbed doses and dose equivalents calculated using the current generation transport codes claim uncertainties under $25 \%$ (NCRP 2006). Uncertainty in the biological consequences of dose rate has been found to contribute about $40 \%$ of the uncertainty in radiation risk estimates although higher LET radiation exhibit decreased dose rate dependence for biological endpoints (Cucinotta et al. 2001). The improvement of radiation protection requires better knowledge of the space radiation field inside the spacecraft, interaction events in shielding and target materials, and biological endpoints based on the known radiation exposures. Much of the uncertainty in risk estimates stem from the unknown relationship between RBE and particle charge and velocity.

## Dose and Risk Assessment

Radiation risk estimates are established for most types of radiation, but large uncertainties exist. Heavy ions impart their kinetic energy by densely ionizing tracks much differently than sparsely ionizing electron tracks produced by photon radiation. This difference is accounted for in dose equivalent calculations using weighting functions that vary by radiation type and tissue type. These weighting factors are derived from the developing knowledge of biophysics and radiobiology and depend on both experimental and epidemiological data. Irradiation characteristics such as dose rate, radiation quality, and target types are the driving forces that determine weighting
factors. The ICRP states that radiation weighting factors $\left(\mathrm{w}_{\mathrm{r}}\right)$ are designed for the practice of radiological protection, and are not intended for specific risk assessment (ICRP 2003). The radiation weighting factor depends on the radiation type and its kinetic energy. It is strongly based on RBE data and is intended to represent stochastic effects following low doses. It must reflect an entire range of LET values for a particle and its secondaries.

Absorbed dose is an average value of the amount of energy deposited in a volume of material by radiation. Dose equivalent is a product of absorbed dose and a radiation quality factor $(\mathrm{Q})$ and predicts the biological damaging ability. Effective dose equivalent is the product of dose equivalent and a tissue weighting factor to describe risk, specifically, to a tissue or organ. This research focuses on radiation quality and the uncertainties it generates for the dose equivalent value. Radiation weighting factor does not account for differences in LET, particle charge, or particle velocity. Quality factor is based on the LET of a radiation, providing detail for radiation protection over a broad range of LET values.

Ions in the GCR spectrum cover a very broad range of LET values. Q varies as a function of the unrestricted LET, representing an average energy lost by a particle as it traverses thin slices of target depth, strongly determined by particle charge and velocity. Unrestricted LET accounts for all energy deposited by a particle, as opposed to the restricted LET that uses a cut-off distance to neglect secondary-energy depositions that occur far away from the primary track. This method provides better analysis than the single value given by $\mathrm{w}_{\mathrm{r}}$. Figure 1 describes how Q varies with increasing LET, reaches
a maximum at $100 \mathrm{keV} \mu \mathrm{m}^{-1}$, and then drops off at higher LET values. The Q value is intentionally biased to be conservative when uncertainty exists in the data.

Figure 1. Radiation quality factor as a function of LET (ICRP 2003).

The reason Q drops off at very high LET is that such densely ionizing radiation tends to kill mammalian cells. This overkill effect increases the chance of experiencing acute radiation effects where non-surviving cells do not become cancerous.

Quality factor is roughly related to the RBE of a radiation, often related to LET. RBE can be studied as a function of stochastic or deterministic effects. It is a ratio of two absorbed doses of two different types of radiation that produce the same effect. For example, if twice as much radiation dose is required by radiation A to kill as many cells as radiation $B$, then the $R B E$ of radiation $B$ is 2 in regard to radiation $A$. Radiation $A$ is generally a reference radiation of Co-60 or Cs-137 gamma or 250 kV x-rays. Cell-kill is
associated with short-term, deterministic effects, while the yield of chromosome aberrations is often assumed to be associated with cell survival and stochastic, cancer risks. In radiobiology experiments, RBE can be designated to describe a variety of biological endpoints. RBE commonly describes the population of surviving cells following radiation exposure. RBE can also be used to describe other target effects, such as the population of chromosome aberrations present in cellular targets following irradiation. Figure 2 displays RBE as a function of LET for several different biological endpoints.

The trends in Figure 2 represent how experimental radiobiology data was used in the development of the Q vs. LET relationship. RBE for heavy ions tends to be largest at low dose; the relevant values are termed $\mathrm{RBE}_{\mathrm{M}}$ (ICRP 2003). The $\mathrm{RBE}_{\mathrm{M}}$ is the ratio of the initial slopes of the dose-effect curves between a radiation of study and a reference radiation. It describes the limit values where the RBE reaches low doses and effects become more difficult to identify. $\mathrm{RBE}_{\mathrm{M}}$ was established to provide a baseline comparison between experiments using different absorbed doses and dose rates.

Figure 2. RBE as a function of LET for various biological targets and endpoints (Cucinotta et al. 2001). Data points represent target effects following exposure to ions of different charge and velocity and largely varying LET. Biological endpoints include cell transformation ( $\bullet$ ), HPRT Mutation ( $\nabla$ ), Dicentrics ( $\mathbf{\bullet}$ ), centric rings ( () , initial isochromatid breaks ( $\mathbf{\Lambda}$ ), complex exchanges ( 0 ), harderian gland tumors ( $\mathbf{0}$ ), skin cancer in rats $(\boldsymbol{\nabla})$. Quality factor $(-)$ is displayed along with the most likely range $(\cdot-)$ and maximum range ( $\cdots \cdot$ ).

Figure 3 shows RBE for a single biological endpoint by different ions having
similar LET values. These results suggest that ion charge and velocity may be as important as rate of energy loss in determining biological effectiveness. Most RBE data are taken from irradiation experiments on mice, rats, and cell cultures. The data suggest as LET increases past $100 \mathrm{keV} \mu \mathrm{m}^{-1}$, the stochastic risks decrease.

Figure 3. RBE and quality factor as a function of overlapping LET values for various heavy ions. (ICRP 2003). Data points represent $\mathrm{RBE}_{\mathrm{M}}$ for each heavy ion at its corresponding LET. The quality factor is displayed ( $\cdots \cdot$ ) as a function of LET.

Dose-rate plays an important part in radiobiology because it allows for cellular repair processes that can occur between subsequent target ionizations. Dose rate effectiveness plays a more significant role for low-LET radiation than for high-LET radiation in cases of cell kill. Compared to the diffuse photon dose, the densely ionizing tracks of a heavy ion isolates its dose to a fewer number of targets, leading to increased cell kill. In the high-Z GCR environment, target traversals are few and far between, leading to very-low dose rate and low total dose compared to the exposures used in most RBE measurements. Carcinogenic effects are the prominent radiation risk factor for space missions. Fluence rates are estimated to be roughly 4 protons $-\mathrm{cm}^{-2}-\mathrm{s}^{-1}, 0.4$ helium
ions $-\mathrm{cm}^{-2}-\mathrm{s}^{-1}$ and 0.04 HZE particles $-\mathrm{cm}^{-2}-\mathrm{s}^{-1}$ at solar minimum when GCR intensities are at their maximum values. This approximates a single mammalian cell being hit by protons once every three days, by helium ions once every month, and by HZE particles once every 300 days (Curtis et al. 1995). RBE ratios may not be as appropriate for understanding biological effects from space radiation. The type of damage, the particle track structure, fluence, and fluence-rate must be considered.

Dose-fractionation or low dose-rate effects on RBE are important topics when considering space radiation. RBE is specific to a cell type and can also show dependency on dose-rate. For low-LET irradiation, the survival curve often shows a shoulder effect at lower doses and this response is often described as sub-lethal damage repair. As LET increases, this effect diminishes. The LET value is an average of a broad range of possible energy deposition events by a traversing ion. Very high energy events are possible, but very unlikely. If an individual cell is only traversed by a heavy ion once every 300 days then the most probable energy loss value is more relevant than the mean. This effect varies for ions of different $Z$ and velocity. Monte Carlo simulations can be used to determine a mean and most probable energy deposition for an ion traversing a target.

The Bethe-Bloch approximation of energy loss shows that ions of different atomic number and equal kinetic energy per nucleon interacting in the same material deposit their energy at different rates since their stopping powers are based on the square of their charge. This approach does not account for processes other than coulomb interactions, such as production of recoil particles and nuclear fragmentation. Based on
the Bethe-Bloch approach, ions of equal LET but different Z must have different velocities. This approach describes energy lost over an incremental distance and can be compared to LET in a thin target. As kinetic energy increases, orbital electrons with a smaller velocity than the corresponding ion velocity will be stripped off, leaving an ion with no electrons and an effective charge equal to its number of protons. This resulting effective charge of the ion determines the magnitude of excitation and ionization of target atoms (Kraft et al. 1992).

The actual amount of energy lost by individual particles passing through a thin absorber can range over several orders of magnitude, and detector thickness strongly influences the shape of the distribution curve for energy loss. For thin target slices, such as the ones used in this research, the shape of the curve can be predicted with Monte Carlo simulations, and can account for range-energy straggling. Range-energy straggling describes the required target thickness for the traversing ion to undergo all probable interactions and energy-loss events.

Fragmentation and electromagnetic ionization and excitation vary for ions having different Z and velocity. Ion fragments and high-energy secondary electrons contribute to the possible energy deposition events. The structure of an ion path can be well described by the locations of the many energy depositions within small volumes representing sensitive cellular targets. Studying track structures of multiple ions at equal LET, or with equal velocity, introduces one possible approach for identifying physical parameters which may predict biological consequences.

As an ion traverses a target, most interaction events are with the target atom electrons and can result in soft, glancing collisions or hard, knock-on collisions. The distance between the traversing charged particle and the target atom is referred to as impact parameter. A soft collision occurs when a charged particle passes an atom at a large impact parameter, and the particle coulombic field excites or ionizes the target atom by the transfer of a few eV . A hard collision occurs when a charged particle passes by an atom at a small impact parameter, interacting with a single electron and imparting much more kinetic energy (Attix 2004). This target electron is called a delta ray and is energetic enough to create its own, separate track. For an ion with a high velocity and very small impact parameter, delta rays can be produced with enough kinetic energy to travel up to several millimeters away from the ion path in tissue or water targets. As ion velocity decreases, delta rays are produced with significantly shorter range. A very broad spectrum of kinetic energies and emission angles is imparted to delta rays, determining where they deposit their dose. Very low-energy delta rays (below 1 keV ) remain near to the ion path, while delta rays of much higher-energy can travel much farther and can create other delta rays.

Ions having equal velocity produce the same spectrum of delta ray kinetic energies, although in different numbers, based on the square of the effective charge of the ion. The resulting delta ray tracks affect the same sized volumes. Figure 4 describes the production of low-energy delta rays for a heavy ion respective to angle of incidence. The electrons of interest in this research have more than 1 keV of kinetic energy, so they are produced primarily in smaller-angle interactions. In Figure 4, delta rays with greater
than 1 keV kinetic energies are represented by the binary collisions with target atoms.
These collisions are strongly dependent on impact parameter and produce delta rays by freeing electrons from the target atoms.

Figure 4. Delta rays are produced when the primary ion passes and receive kinetic energy based on the angle and impact parameter. The data presented here represent a 30 MeV oxygen ion traversing a water target (Kraft et al. 1992). Cross section curves are presented for increasing interaction angles of the traversing ion.

The sharp, discrete peaks are from Auger processes (for both the target and projectile atoms) where an excited atom emits an electron. Lower-velocity ions suffer some energy loss to electron pickup (and loss), as they approach their Bragg peak. This effect creates the auger and electron loss peaks seen in Figure 4. Higher-velocity ions yield only the binary, target auger, and soft collision peaks.

Dose surrounding the ion path is primarily due to the energy deposition by binary collision electrons. Electron energy, $E_{e}$, the emission angle, $\theta$, and the particle energy, $E_{p}$, are correlated according to Equation 1 for small impact parameter.

$$
\begin{equation*}
E_{e}=\frac{4 m_{e}}{m_{p}} E_{p} \cos ^{2} \theta \tag{1}
\end{equation*}
$$

The terms, $m_{e}$ and $m_{p}$, are the electron and projectile mass, respectively (Kraft et al. 1992). Higher-energy electrons are more forward directed, while lower-energy electrons are emitted at a larger angle from the ion path. Low-energy electrons are emitted isotropically for large impact parameters.

Delta rays with energies below 100 eV travel only a few nanometers from the primary ion track and create ionization regions, commonly referred to as 'spurs'. Electrons with energies of 100 to 500 eV electrons can extend $\sim 7 \mathrm{~nm}$ from to the primary track, creating a track known as a 'blob'. Electrons with energies between 500 and 5000 eV have short tracks, and electrons with energies above 5000 eV have enough range to create tracks that take them away from the primary ion path. These high-energy electrons can go on to create additional delta rays producing the spur and blob ionization
regions. Figure 5 displays electron energy vs. penetration distance in water. Electrons having less than 1 keV are expected to be contained within $\sim 20 \mathrm{~nm}$.

Figure 5. Electron penetration distance in water vs. kinetic energy (Meesungnoen et al. 2002). Monte Carlo-simulated work represented by solid line (-), with errors bars showing the $95 \%$ confidence intervals.

The different data points and trend lines represent different theoretical models and referenced experimental data. This information is only used as a guideline for setting up the appropriate dosimetry approaches utilized in this research.

Electron tracks establish the energy deposition and spatial distribution of initial water and DNA radicals. DNA single and double strand breaks are created either directly by ionization from charged particles or indirectly by the diffusion of free radicals produced by excited atoms. Water radiolysis is important for the indirect action of radiation. The damage produced by water-derived free radicals is chemically modifiable damage and accounts for $\sim 70 \%$ of the damage from low-LET irradiation (Chatterjee and Holley 1992). The chemical track is modified over time by diffusion and reactions of chemical species. In living cells, the reactive species undergo diffusion and chemical reaction over $10^{-12}-10^{-6} \mathrm{~s}$ and have a diffusion range of $\sim 4 \mathrm{~nm}$ (Bolch et al. 1990).

Ionizing radiation is extraordinarily efficient in causing biological consequences compared to that caused by oxidizing chemicals and the body's own endogenous processes. The non-randomness of energy delivery to sensitive sites, such as DNA, causes that effect (Goodhead 2006). Ionization sites tend to be clustered at the end of electron tracks and diffusion of water radicals expands those clusters by a few nanometers. Low-LET radiation is sparsely ionizing, but about $25 \%$ of energy is deposited in clusters at the ends of delta ray tracks. Double strand breaks (DSB) are commonly produced from this clustering of ionizations resulting from direct and/or indirect effects. High-LET tracks consist of a densely ionizing core and a low-LET delta ray penumbra, each contributing roughly $50 \%$ of the total dose. Ionization density in the track core is extremely high, and some of this energy is carried away by delta rays. Very-low energy delta rays that create the 'blobs' and 'spurs' lie in the vicinity of the
track core. These delta rays deposit their kinetic energy across very short distances and can create clustered lesions when the primary ion traverses a chromosome. Sensitive cellular-target volumes are described in Table 2.

Table 2. Dimensions of sensitive targets on the cellular scale (Goodhead 2006).

| Scale | Biological Target |
| ---: | :--- |
| $100 \mu \mathrm{~m}$ | Adjacent cells are damaged |
| $10 \mu \mathrm{~m}$ | Cell nucleus. Large insult, or possibly none. |
| $1 \mu \mathrm{~m}$ | Chromosomes. Correlated damage in separate chromosomes |
| 100 nm | Chromatin. Correlated damage fragments |
| 10 nm | Clustered damage, fragments |
| 1 nm | Recombination, bi-radical reactions |

The complexity of a lesion generally depends on the LET of the charged particle. Clustered damages are found when there is more than one break in a DNA strand within 2 - 10 base pairs (Goodhead 2006). Complex breaks can occur when there are multiple breaks on one or both strands of the DNA helix, producing single strand breaks (SSB) and DSB. These lesions are harder to repair and promote an increase in the biological effectiveness of ionizing radiation.

Heavy ions introduce a higher fraction of complex lesions, leading to chromosome breakage and possible rearrangement. This damage can progress to a point where no repair is possible and the cell dies. The number of residual DNA breaks in a surviving irradiated cell is one characteristic of radiosensitivity and varies by cell type and radiation type. The cell cycle also plays an important role, and dose rate or fractionation can interact with cell cycle changes to enhance or diminish biological
response. Aberration type, such as complex and simple-type exchanges, must be considered to establish RBE values. Increasing LET usually increases the ratio of complex to simple-type exchanges. RBE for ions of equal LET is better established for a cell killing scenario than for chromosomal aberrations (Ritter and Durante 2010). It is stated in NCRP Report No. 153 (2006) that very few experiments have studied the possible variation of biological effects of radiations with a fixed-LET value but different combinations of ion charge and velocity. Katz noted that such effects are masked at high doses where on average more than one particle traverses a cell (Katz et al. 1971). The full spectrum of secondary particles must be simulated and scored on a biologically relevant scale to effectively assess the effect of track structure on individual damaging events within single cells. The biological effectiveness of radiation also depends on dose-rate because cell cycle responses have more time to repair the cell during low-dose rate irradiation. This research analyzes the radiation dose for individual events for seven different GCR ions at prescribed kinetic energies and stopping powers. Cell type and time scales are not simulated and are not considered part of the track structure influence on damaging ability.

## Analytical Approaches

To effectively describe the track of heavy ions through a target, interactions must be accounted for on nanometer to millimeter scales. Energy deposition events vary both longitudinally and radially from the primary ion path. LET along the path of the ion is characteristic of the immediate stopping power of the particle and the trajectories of
secondary radiations. As mentioned in a previous section, higher-energy delta rays are more forward directed and follow straighter paths. The lower-velocity ions used in this research experience increasing stopping power because the target depths are large in relation to their total range. Those with higher velocities show no increase in stopping power when traversing a 1 mm thick target.

The radial dose surrounding an ion track is well described by an 'amorphous track' model. In this type of model, track structure is described by the radial distribution of local dose around the primary particle path due to the primary particle and its delta rays. The structure of the track lies inside coaxial cylindrical shells about the ion path and is traversed by secondary electrons ejected from the medium by the passing ion. The ion track consists of a core and a penumbra region. The core is a region of very high-energy density where many soft collisions transfer small amounts of energy (Chatterjee and Schaefer 1976). The core is estimated to have a radius, $r_{c}$, proportional to the velocity $(\beta)$ of the particle and is described (Chatterjee and Schaefer 1976) by the equation:

$$
\begin{equation*}
r_{c}=0.0116 \beta \mu \mathrm{~m} \tag{2}
\end{equation*}
$$

Energy is deposited in the core by excitation of individual target atoms or in collective oscillations of electrons when the heavy particle passes. These soft-collision interactions are much more frequent than hard collisions but transfer much less energy (Chatterjee and Schaefer 1976). Based on the Chatterjee equation, most GCR have a
core radius ranging from about 1 to 10 nm . The core radius is not exact and is only meant to establish a boundary between delta rays that essentially have no range with those that do. Some secondary electrons may be included within the core and have only a few eV of kinetic energy.

Knock-on collisions create the delta-ray field, known as the penumbra, that can be depicted as a cylindrical shell region along the axis of the primary particle direction. The penumbra encompasses a region of ionizations whose energy decreases exponentially with increasing distance from the primary particle path. A wider delta ray penumbra imparts a lower local ionization density for the same total dose (same LET) to a large enough target. The penumbra radius, $r_{p}$, is characterized in the following equation (Chatterjee and Schaefer 1976):

$$
\begin{equation*}
r_{p}=0.768 \mathrm{E}-1.925 \sqrt{E}+1.257 \mu \mathrm{~m} \tag{3}
\end{equation*}
$$

where E is the kinetic energy of the particle in $\mathrm{MeV} \mathrm{n}^{-1}$. The penumbra radius does not extend to the maximum delta ray range because there are so few electrons reaching this distance, the dose is essentially zero. Figure 6 characterizes the core and penumbra regions by the black and white circles, respectively. Delta rays with ranges smaller than the core are not depicted and considered part of the core, while energy deposited outside of the penumbra is not considered.

Figure 6. Cross-sectional view of the ion track with escaping delta rays that form a penumbra (Chatterjee and Holley 1991). The dark circle represents the track core.

The amorphous track model yields a radially-dependent dose that decreases as $\mathrm{r}^{-2}$ (r being the distance perpendicular from the primary particle path). This approach generates radial dose values that would be expected from the delta rays seen in Figure 6. Chatterjee presented Equations 4 and 5 for energy density ( $\mathrm{kev} \mu \mathrm{m}^{-2}$ ) within the core $\left(\mathrm{Q}_{\mathrm{c}}\right)$ and penumbra $\left(\mathrm{Q}_{\mathrm{p}}\right)$ (Chatterjee and Schaefer 1976):

$$
\begin{align*}
& \mathrm{Q}_{\mathrm{c}}=\frac{L E T_{\infty} / 2}{\pi r_{c}^{2}}+\frac{L E T_{\infty} / 2}{2 \pi r_{c}^{2} \ln \left(\sqrt{2.718} r_{p} / r_{c}\right)}  \tag{4}\\
& \mathrm{Q}_{\mathrm{p}}=\frac{L E T_{\infty} / 2}{2 \pi r^{2} \ln \left(\sqrt{2.718} r_{p} / r_{c}\right)} \tag{5}
\end{align*}
$$

where $r$ is an independent variable denoting radial distance from the center.
The delta ray distribution formula, discussed by Butts and Katz (1967), treats all electrons as free from target atom orbitals, and delta rays are considered to scatter at an angle dependent on their kinetic energy (w) relative to the maximum possible delta ray energy ( $\mathrm{w}_{\mathrm{max}}$ ), following the equation (Butts and Katz 1967),

$$
\begin{equation*}
\cos ^{2} \theta=\frac{w}{w_{\max }} . \tag{6}
\end{equation*}
$$

The Katz model provides a theoretical model for determining delta-ray energy fluence. This provides some added detail to the dosimetry within the amorphous track model by detailing individual delta-ray tracks within the cylindrical regions. The following equation:

$$
\begin{equation*}
d n=\frac{c z^{* 2}}{\beta^{2}} \cdot \frac{d w}{w^{2}} \tag{7}
\end{equation*}
$$

can be used to determine the number of delta rays per unit path-length having kinetic energy within a spectrum of $w+d w$. In this equation, $w$ represents electron kinetic energy, $Z^{*}$ is the effective charge of the ion, and C is described in the reference as having a value of $0.0085 \mathrm{keV}^{-1}$ (Butts and Katz 1967).

The amorphous track model simplifies the Butts and Katz theory by assuming all delta-rays travel perpendicularly to the primary particle direction. This model does not
predict individual delta-ray events, only the average energy deposited at a radial distance that would be expected from delta-ray traversals. The amorphous model has been developed with theoretical and experimental data and provides a fairly accurate estimation of how dose extends radially from the ion path. Originally established using proton data, the model was extended to heavier ions by finding that the radial distribution of local dose varies as a function of $Z^{2} / \beta^{2}$, where $Z$ is atomic number and $\beta$ is particle velocity divided by the speed of light (Katz 1978).

The amorphous track model estimates the radial dose surrounding an ion path at a point where delta-ray equilibrium exists, providing dose estimates from very small to very large radii. This method provides an instantaneous radial dose estimate and does not account for deviation of the primary particle away from the track axis as it traverses a target. When studying a real target, ions of higher velocity require increased target depth to achieve delta-ray equilibrium. However, the chances of scattering and nuclear fragmentation both increase as the particle traverses deeper into a target. Track structure continues to evolve along the particle path, so the radial dose depends on more than just delta rays. Of course, the most significant source of ionizations lies within the core or just outside because electron fluence is highest. Farther away from the core, delta-ray events are much more diffuse, similar to those produced by x and gamma rays. The radial dose distribution indicates the lateral spread of the particle track but ignores the stochastics of possible energy-loss events along the track (Cucinotta et al. 1998).

Monte Carlo methods for simulating individual particle traversals are an effective method for detailing track structure. Instead of calculating ionization densities,
individual energy deposition events and particle fluences are simulated. This information is used to correlate the spatial distribution of energy deposited with reference to biological targets. Monte Carlo methods can be used to report the statistical nature of the location of energy deposition sites on the DNA molecules, the amount of energy deposited, the spectrum of particles involved, and the diffusion of water radicals (Holley and Chatterjee 1996).

On the cellular level, variations in the particle trajectories of different ions cause a change in energy deposition and the resulting target effects. The spatial distribution of energy deposition (in a cell nucleus) from a high-atomic number, high-energy (HZE) particle track depends on the traversing particle, cellular targets, recoil nuclei, nuclear fragments, and delta rays. Targets of interest are DNA strands, with a diameter of about 2 nm , that make up a chromosome that is about $1.4 \mu \mathrm{~m}$ thick. Radiation directly strikes the target, disrupting molecular bonds, and is described as a direct effect. Damage is produced by both direct and indirect energy deposition events. Radiation can interact with the water inside the cell to create free radicals that can then migrate to damage DNA. Diffusing water radicals created from interactions in the water surrounding the DNA describes the scavengeable component of DNA damage (Nikjoo et al. 1998). The diffusion length of free radicals in a cellular media is commonly estimated at about 3-4 nm (Goodhead 2006; Chatterjee and Holley 1992), relevant to DNA base pair volumes. Radical diffusion can be estimated as a cylindrical region around the constant slowingdown path of a delta ray. The number of free radicals created is proportional to the energy deposited along a track. It is expected that larger penumbras will produce a
larger field of radicals, but the density of radical formation may actually be of more concern. Monte Carlo methods can simulate the ionization of water molecules and their diffusion leading to strand breaks (Holley and Chatterjee 1996). Turner used Monte Carlo techniques to predict radical diffusion following the initial physics interactions in a medium (Turner et al. 1991). This 1991 study modeled a charged-particle path along with all associated secondary electrons. These particles were transported, step by step, until their energies fell below the minimum threshold for electronic transitions in liquid water. Each interaction was capable of initiating water radiolysis, where the resulting radical molecules could be tracked to a point of recombination leading to radical diffusion coefficients.

Clustering of ionizations on a DNA strand has been shown to produce lesions that are the most difficult to repair (Goodhead 2006). An energy deposition threshold of 17.5 eV is a common estimate for the amount of energy deposited in one sugarphosphate volume to create a single strand break (Nikjoo et al. 1998). That local energy deposition estimate is representative of base damage as well as strand damage (Goodhead 2006). DSB can be predicted based on energy deposition values in a target in the penumbra or by simulating two events on a DNA strand that happen to lie within a few base pairs distance from each other. A separation of 30 base pairs is commonly set as the maximum separation between two single strand breaks to create a DSB (Charlton et al. 1989). Particle tracks impart a random orientation of ionizations leading to clustering of DNA lesions, which complicates repair. An absorbed dose of 1 Gy of $x$
rays is estimated to create 40 DSB, 150 DNA crosslinks, 1000 SSB , and 2500 base damages (Goodhead 2006).

To relate the variations of track structure across different ion species and different velocities (but similar LET), charged particle tracks can be modeled by partitioning the energy deposition between primary track core and delta rays (Holley and Chatterjee 1996). The amorphous track model is restricted in that it only considers a cylindrical (or spherical) geometry surrounding the particle track and ignores the broad range of possible energy deposition events by a varying number of secondary particles. This research includes this range of events with frequency distributions of energy imparted to small volumes surrounding the primary particle path. Information from the amorphous track model can be compared with Monte Carlo simulation of energy imparted in a volume at some radial distance from the primary particle track.

Microdosimetry is the measurement of energy deposition events and particle fluence on scales relevant to cells. Tissue equivalent detectors containing low pressure gas can be placed within a biological target to simulate a cell-sized volume. This method allows dosimetry to be performed without disturbing the radiation field. For the purposes of this research, dosimetry quantities are scored in, or near, a heavy ion track in a water medium to generate the dose and number of particle traversals experienced by a cell nucleus. By placing the detector at different distances from a particle track, radial dose can be calculated.

Many radiation biology experiments irradiate thin layers of cells in culture, thin enough so that the LET does not vary appreciably. A major topic of discussion is track
structure in thin targets, similar to a plane of plated cells in culture. The track structures are used to make estimates for energy depositions in the cell nucleus. Magnitude of energy deposited and clustering of events are the main criteria for determining damaging effects. The most probable energy deposition (rather than the mean) can be determined by Monte Carlo energy distribution simulation, giving more relevant results for very low fluence applications. The most probable value is generally less than the mean and should be used to calculate the dose that a cell would receive by a single ion traversal. The improbable and very high-energy loss events exaggerate the mean value as particle velocity increases. The Monte Carlo approach used in this research details the energy fluence of particles induced by a traversing GCR in a water target. Data are then used to make predictions on the relative damaging ability of different GCR for comparison with theoretical models.

Damaging ability of a track structure can be described by the ionization density within a cell nucleus that leads to DNA strand breakage, free radical production, and clustering of ionizations. Damage can be assessed by simulating the probabilities of ionization density and particle traversal frequencies within a large group of cells traversed by an ion.

## CHAPTER III

## METHODS

The goal of the research is to show differences in the track structure of different ions by modeling particle fluence and energy deposition events on a biologicallyrelevant scale. This analysis utilizes Monte Carlo simulation of GCR in water targets to model track structure and the corresponding interactions in targets similar to that used in the amorphous track model and microdosimetry. The FLUKA code can be used to provide the track structure for all interactions, detailing the paths of particles and their secondaries. Mean and most probable energy loss values are established from simulating large numbers of particle histories.

The first analysis in this research focuses on the track structure of GCR having equal stopping power. The Bethe-Bloch equation was used to determine particle velocities for ions with stopping powers of $100 \mathrm{keV}_{\mu \mathrm{m}}{ }^{-1}$ in water. This value was chosen because it correlates with the peak LET value on the quality factor curve, meaning it is the most detrimental. Kinetic energy values for each ion are as follows:

- Beryllium-8: $\quad$ 6.80 $\mathrm{MeV} \mathrm{n}^{-1}$
- Carbon-12: $\quad 18.48 \mathrm{MeV} \mathrm{n}^{-1}$
- Oxygen-16: $\quad 37.52 \mathrm{MeV} \mathrm{n}^{-1}$
- Magnesium-24: 106.3 $\mathrm{MeV} \mathrm{n}^{-1}$
- Silicon-28: $\quad 164.0 \mathrm{MeV} \mathrm{n}^{-1}$
- Calcium-40: $631.5 \mathrm{MeV} \mathrm{n}^{-1}$
- Titanium-48: $1582 \mathrm{MeV} \mathrm{n}^{-1}$

The energy and range of nuclear fragments and delta rays produced in the target are strongly influenced by these primary particle velocities. As a result, there are variations in the energy deposited in a target for the different ions. For the second part of the research, GCR are compared with equal velocity and different LET. The velocity, presented as kinetic energy per nucleon, was chosen to be $600 \mathrm{MeV} \mathrm{n}^{-1}$ because it approximates the most probable GCR velocity in the space environment (NCRP 2006). Variations in track structure for equal velocity ions are only dependent on Z .

The FLUKA code was used to model the LET of each ion traversing a $1 \mu \mathrm{~m}$ thick water target slabs. The first analysis was to calculate the mean value of the spectrum of energy deposition events by the ion. This should be quite close to the 100 $\mathrm{keV} \mu \mathrm{m}^{-1}$ stopping power predicted by the Bethe-Bloch equation. The most probable value is taken from a histogram of the energy loss spectrum and is relevant in analyzing individual particle traversals. Energy deposition distributions are performed with and without consideration for delta-ray tracks. To account for delta-ray equilibrium, electron fluences across thin slabs (perpendicular to the primary ion track) were scored at multiple depths inside a thick target. These data allow for the analysis of primary particle scatter, fragment production, and the build-up of delta rays toward equilibrium. The next step was to simulate those energy loss events on a scale relevant to cellular targets to create the track structure model.

## Simulation Model

The FLUKA code can be used to account for all the particles involved in track structure analysis relevant to radiation biology studies. Interaction cross sections are specific enough to account for the broad kinetic energy spectrum of GCR. The code can be used to simulate delta-ray transport in complicated geometries and modeling their corresponding trajectories and energy deposition distributions.

The first target geometry for irradiation was made up of coaxial cylinders, parallel to the ion path and similar to the amorphous track model approach. Energy deposition at increasing radii was modeled along the primary particle track to establish a smooth trend of dose vs. radial distance to provide dosimetry for critical volumes as small as those found within a cell nucleus. Unlike the amorphous track model that gives an energy density value relative to radial distance, Monte Carlo models provide the spectrum of energy deposited by individual events in the regions surrounding the particle track. This process accounts for energy deposited based on particle type to provide comparisons at increasing depths in a target.

To develop sufficient data statistics, GCR traversals are modeled as a pencil beam penetrating a cylindrical slab of water. In this case, the primary particle is traveling into the page at the center of the figure. By simulating the primary particle through the same entrance point for each simulation, the delta-ray penumbra forms around the core axis. This slab is constructed of cylindrical shells of increasing radius, as shown in Figure 7 (not to scale).

Figure 7. Cross-sectional view of the cylindrical shell geometry.

The dimensions were chosen to represent significant distances within a cell nucleus up to a few cell diameters. The innermost shell has a radius of 5 nm , roughly the size of the track core. The shells extend up to 1 cm radius to account for the very high-energy delta rays and scattering nuclear fragments. The slab is perpendicular to the beam axis, with a thickness of $1 \mu \mathrm{~m}$. Multiple slabs, with the same thickness, are placed inside a larger target to provide particle fluence data as delta rays build toward equilibrium. This may require up to several millimeters of depth for higher-energy ions. These dimensions are intended to provide energy fluence data from a DNA-sized region of interest all the way up to multiple cell diameters.

Using the SCORE and USERBDX functions, the FLUKA code estimates the total energy deposited, frequency of energy deposition events in each region, and the particle fluence for each cylindrical boundary. Particle fluence information is sorted by particle type and kinetic energy when crossing the cylindrical boundaries, in conjunction with energy deposition scoring for each region of interest. Data can be scored by
particle of interest, so the primary emphasis is placed on charged particles to account for the primary particle, charged fragments, and delta rays. Data output provides energy fluence and energy deposition information within the delta-ray penumbra produced by a GCR as well as its fragments. This information describes how the path of the primary ion is affected as it traverses the water medium. Primary and secondary ions will experience some scatter away from the initial beam axis, diffusing the track core measurements within the 5 nm cylinder. FLUKA input files are displayed in Appendix A for several irradiation scenarios and target geometries.

The FLUKA code cannot be used to follow the paths of electrons with kinetic energies below 1 keV . For the purposes of this research, the range of electrons below 1 keV is assumed to remain very near to the primary track core. The outer edges of the core are assumed to consist of electrons below a few keV and of water radicals, both contributing to very high-ionization density. Those low-energy electrons produced in ionizations farther away by high-energy delta rays are not expected to have enough range to cross the corresponding region boundary, and their energy is deposited along the path of the parent particle. This research assumes that the production of water radicals affects such small distances ( $\sim 4 \mathrm{~nm}$ ) that they are considered to react at the point of production. The FLUKA code is not capable of simulating the diffusion of chemical species.

The second simulation geometry utilizes the USERBIN function to provide energy deposition and particle fluence on a target-by-target basis. This approach generates dosimetry data for cell nuclei-sized volumes, to provide analysis of the number
of sensitive targets being affected by a traversing ion. A thicker target accounts for the necessary delta-ray buildup for the higher-energy ions and gives better analysis for damage to a group of targets. Since nanometer volumes are not accounted for in this part of the research, the primary ion has more room to scatter off its path without negatively affecting the results. A water cube, with 1 mm edges, contains a mesh of many small cube-shaped voxels. Each voxel has $10 \mu \mathrm{~m}$ edges, giving a volume similar to a cell nucleus. By simulating particle traversals within this geometry using the FLUKA code, the probabilities for dose and number of particles traversing each voxel can be determined. The geometry is not meant to perfectly simulate a group of cells, only approximate the relevant biological target volumes. The geometry is depicted in

## Figure 8.

Figure 8. Mesh cube geometry for taking microdosimetry measurements inside a 1 mm thick cube. The red circle represents the incident primary ion.

The target consists of 1 million voxels, many of which may not receive any dose. By modeling the traversal of 200,000 ions (of the same type) through the same point, frequency distributions of dose and particle fluence can be determined with appropriate statistics. Dose and particle fluence from electrons is recorded in each voxel.

The final target geometry for this research is a cylindrical mesh with a $5 \mu \mathrm{~m}$ radius. The purpose for this geometry is to provide additional target hit data, using the USERBIN function, for very small volumes within the cube mesh. The cylinder mesh is contained inside of a single $1,000 \mu \mathrm{~m}^{3}$ voxel from the $1 \mathrm{~mm}^{3}$ geometry. The cylindrical mesh is $10 \mu \mathrm{~m}$ long and simulates 1 million target voxels that are nearly cube-shaped, having 10 nm edges. Similarly, the geometry can be used for radial dose comparison with the amorphous track model, as well as the cylindrical shell model previously described.

## Analytical Methods

The FLUKA code was used to calculate the energy deposited in each cylindrical region, so results were compared with expected radial dose calculated by the amorphous track model. The next step was correlating the radial dose distribution with the spectrum of energy depositions in each cylindrical region. This research also treated the penumbra and core regions separately but accounted for individual events rather than relying on an average. Individual energy deposition events can be described radially. Delta-ray production was compared with the Katz delta-ray distribution formula. These
electrons were scored as they crossed each region for the cylindrical model and the mesh cube.

The cube geometry provided data for individual cell nucleus-sized target events to simulate delta-ray effects on surrounding cells. Dose per voxel and the number of particle traversals per voxel were then compared across the different ions to establish damaging ability. The mesh cylinder provided data inside the $5 \mu \mathrm{~m}$ radius of a cell nucleus. The target voxels represented DNA strand-sized volumes; dose, number of particle traversals, and dose per electron were scored as well for each target.

The biological parameters considered for this research were ones of target geometry and dosimetry effects. The goal of the research was to determine the physical damaging ability of different ions relative to each other. Delta-ray energy fluence and local dose values identified the potential for damage occurring in the target. No consideration was made for damaging effects across different types of cells or with regard to dose-rate effects. The cylindrical radial dose geometry was intended to relate FLUKA results with commonly used radial dosimetry of heavy ions. The USERBIN mesh geometries provided more accurate data, accounting for target hits. Damaging ability was then compared on both intercellular and intracellular scales.

## CHAPTER IV

## RESULTS

## Energy Deposition Trends

Monte Carlo simulation provides the user with more options for scoring spatial distributions of dose and particle fluence than the amorphous track model. Simulations also allow for studying the dose as a function of particle fluence through individual target regions. This section presents the results from the particle simulations for each irradiation scenario and target geometry.

The first analysis describes the energy deposition trends for several ions traversing thin slabs of water. Figure 9 depicts ions with calculated stopping powers of $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ using the Bethe-Bloch approach, while Figure 10 shows ions of equal velocity ( $600 \mathrm{MeV} \mathrm{n}^{-1}$ ) but different stopping powers.

Not all ions are represented in the Figure 9 for visual clarity, but the trend is clear. The data presented here describe energy deposited by a traversing ion, whose secondary particles are assumed to deposit their energy at the point of production. There is no energy escaping the target, except for that of the primary ion, so this figure represents the total value for each energy-loss event.

Figure 9. Spectrum of energy deposition events by ions with stopping powers of 100 $\mathrm{keV} \mathrm{um}^{-1}$ in a $1 \mu \mathrm{~m}$ thick water slab. The curves represent the frequency of total energy deposition by individual particles averaged over the total number of particles simulated.

For ions of equal stopping power, the mean value of energy deposition is roughly the same, but the spectra have different shapes. The most probable energy deposition value is located at the peak of each curve. Most probable values describe the most likely energy-loss events for individual primary particle traversals.

Figure 10 displays the same comparison as Figure 9, but for ions with equal velocity ( $600 \mathrm{MeV} \mathrm{n}^{-1}$ ). There are similar energy deposition trends for these ions, but there is a difference in magnitude of energy deposited, based on the ions' charge $\left(Z^{2} / \beta^{2}\right)$. In this case, $\beta$ is nearly identical for these ions, as its calculation depends only slightly on the number of neutrons held by each ion. The reason the lower-velocity ions deposit lower values of energy, is because there is decreased secondary-electron production due to decreased effective charge of the primary ion.

Figure 10. Spectrum of energy deposition events in a $1 \mu \mathrm{~m}$ thick water slab for ions having equal velocities of $600 \mathrm{MeV} \mathrm{n}^{-1}$. The curves represent the frequency of total energy deposition by individual particles averaged over the total number of particles simulated.

Energy loss described by a calculated stopping power is not necessarily the energy imparted to a target. The data reflect total energy deposition per event and frequency is averaged over the total number of primary particles traversing the target. The effect of velocity is very apparent in both Figures 9 and 10. As in Figure 9, the higher velocity ions experience energy deposition events up to several MeV . As a result, there are very rare events representing very high-energy loss of a few MeV that significantly increase the average value representing LET. When cells are only traversed by a heavy ion every few days or weeks, the very high-energy interactions are too rare to be concerned with and can be neglected for risk analysis. The resulting LET is shown to decrease, and the focus should be placed on the most probable value of energy
deposition. The most probable energy deposition value for an ion decreases with increasing velocity since it is not influenced by the high-energy events.

Table 3 displays the average and most probable energies imparted to a $1 \mu \mathrm{~m}$ thick water slab as simulated using the FLUKA code. Ions with equal stopping power produce similar mean values but different most probable values of energy deposition. The most probable value depends strongly on the ion velocity. The LET of the 600 MeV $\mathrm{n}^{-1}$ ions are presented to display the effect of Z on total energy deposition in the slab. In this case, the $\beta^{2}$ value is nearly identical for these ions, and it was determined that their energy deposition values do, in fact, vary as a function of $Z^{2}$.

Table 3. Mean and most probable energy deposition in $1 \mu \mathrm{~m}$ thick water slabs. The ions had either $100 \mathrm{keV} \mathrm{um}^{-1}$ stopping power or $600 \mathrm{MeV} \mathrm{n}^{-1}$ kinetic energy.

| Ion | $\mathrm{Be}-8$ | $\mathrm{C}-12$ | $\mathrm{O}-16$ | $\mathrm{Mg}-24$ | $\mathrm{Si}-28$ | $\mathrm{Ca}-40$ | $\mathrm{Ti}-48$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $100 \mathrm{keV} \mathrm{\mu m}^{-1}$ <br> Mean Value | 99.07 | 99.38 | 99.69 | 100.29 | 100.21 | 98.35 | 94.26 |
| $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ <br> Most Probable Value | 99.07 | 90.91 | 86.42 | 82.15 | 80.09 | 76.14 | 72.37 |
| $600 \mathrm{MeV} \mathrm{n}^{-1}$ <br> Mean Value | 3.96 | 9.01 | 15.97 | 36.08 | 49.05 | 100.48 | 121.46 |
| $600 \mathrm{MeV} \mathrm{n}^{-1}$ <br> Most Probable Value | 2.69 | 6.2 | 11.38 | 26.27 | 36.98 | 79.08 | 99.34 |

Figures 9 and 10 describe the energy lost by charged particles traversing water, but this is not the entire picture. Ion interactions in the target produce secondary radiations that do not necessarily deposit their kinetic energy at the point of production. Much of this energy can be transferred to delta rays that can escape the target, reducing the local dose. The FLUKA code allows the user to simulate secondary electron tracks
following the collisions that make up the LET values shown above. Many dose readings, at increasing depth, were taken to study the buildup of delta rays towards an equilibrium state. This state occurs when the delta rays that escape out of the downstream face of the target are replaced by delta rays coming in from the upstream face. Delta-ray equilibrium is established based upon the primary ion velocity but requires significantly less depth than predicted by the highest energy delta ray.

When the highly energetic delta rays escape the thin $1 \mu \mathrm{~m}$ target slab, the energy that is deposited locally shows a different trend. Figures 11 and 12 show the energy deposition curves for Si-28 and O-16 traversing multiple target thicknesses. To recapture the energy lost to delta rays, targets are placed deeper inside the water medium, allowing for delta-ray buildup. The data are presented with the stopping power curves discussed earlier. The other curves show the significant change in local energy deposition that occurs when delta-ray buildup is accounted for. The electrons produced in the very large collisions no longer deposit all of their energy within $1 \mu \mathrm{~m}$.

At increasing depth in a water medium, the target slabs receive an increasing amount of delta-ray buildup, which eventually reaches equilibrium. Increased depths display more high-energy events than the $0-1 \mu \mathrm{~m}$ depth, meaning delta rays that are created at shallow depths deposit their energy deeper into the target. The curve never completely resembles the stopping power curve at high energies because secondaries produced in these high-energy reactions are very rare and have widely varying ranges.

Figure 11. Si-28 ion traversing $1 \mu \mathrm{~m}$ thick target slabs at increasing depth in water medium. The ion had a calculated stopping power of $100 \mathrm{keV} \mathrm{um}^{-1}$. The curves represent the frequency of total energy deposition by individual particles averaged over the total number of particles simulated. Different curves represent different depths of the target slab to detail delta-ray buildup.

In Figure 12, the O-16 ion appears to have reached delta-ray equilibrium by 50 $\mu \mathrm{m}$ depth, while the $\mathrm{Si}-28$ ion, in Figure 11 hasn't reached delta-ray equilibrium at 100 $\mu \mathrm{m}$ depth. The higher velocity $\mathrm{Si}-28$ ion requires larger depths to reach delta-ray equilibrium.

Figure 12. O-16 ion traversing $1 \mu \mathrm{~m}$ thick target slabs at increasing depth in water medium. The ion has a stopping power of $100 \mathrm{keV} \mathrm{um}^{-1}$. The curves represent the frequency of total energy deposition by individual particles averaged over the total number of particles simulated. Different curves represent different depths of the target slab to detail delta-ray buildup.

Table 4 describes the energy deposited in $1 \mu \mathrm{~m}$ thick slabs at increasing depths by the ions having $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping power. Higher velocity ions require significantly thicker targets to achieve delta ray-equilibrium. The Be-8 ion exhibits a lower LET value in FLUKA data than calculated by the Bethe-Bloch approach. The curves in Figures 11 and 12 do show that energy deposition trends reach equilibrium after much less target depth than predicted by the range of the highest energy delta ray. The Si-28 ions reach this point around $100 \mu \mathrm{~m}$, while $\mathrm{O}-16$ ions do by $50 \mu \mathrm{~m}$ depth.

Table 4. Energy deposition, accounting for delta-ray escape, for ions having equal stopping powers of $100 \mathrm{keV} \mathrm{um}^{-1}$. Maximum energy delta rays, and their range, are displayed and depend on the kinetic energy of the primary particle.

| Ion | $\mathrm{MeV} \mathrm{n}^{-1}$ | Max Energy Delta (keV) | Range in$\mathrm{H} 2 \mathrm{O}(\mu \mathrm{~m})$ | Energy Deposited (keV) in $1 \mu \mathrm{~m}$ slabs |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | 0-1 | 10-11 | 20-21 | 30-31 |
| Be-8 | 6.8 | 14.86 | 5.15 | 84.22 | 91.56 | 90.28 | 91.55 |
| C-12 | 18.48 | 40.63 | 29.2 | 87.44 | 98.55 | 99.87 | 100.92 |
| O-16 | 37.52 | 83.31 | 98 | 84.88 | 95.32 | 97.22 | 99.51 |
| Mg-24 | 106.27 | 244.4 | 640 | 82.08 | 91.18 | 92.83 | 95.3 |
| Si-28 | 164 | 388.2 | 1200 | 80.64 | 89.37 | 90.85 | 93.43 |
| Ca-40 | 631.5 | 1837 | 7000 | 77.22 | 84.93 | 86.07 | 88.61 |
| Ti-48 | 1582 | 6345 | 32000 | 74.16 | 81.05 | 82.2 | 84.56 |

As seen in Figure 10, energy deposition spectra exhibited similar shapes and trends for ions of equal velocity when delta rays were not transported. The differences in LET were due to increased production of ionizations that are a function of $Z^{2}$. When delta rays were transported, the effect of delta-ray loss affected the energy deposition trends experienced by ions of equal velocity. Figure 13 displays those trends as the ions traversed a $1 \mu \mathrm{~m}$ slab at $30 \mu \mathrm{~m}$ depth in water.

Each energy deposition value consists of the total energy deposited by a single ion, averaged over the total number of ions simulated. The energy deposition value is dependent on the charge of the primary particle, so lower charge ions deposit less energy. As shown in Figure 13, lower charge ions also experience the very-high energy deposition events when high-energy delta rays are produced.

Figure 13. Energy deposition by $600 \mathrm{MeV} \mathrm{n}^{-1}$ (equal velocity) ions traversing $1 \mu \mathrm{~m}$ thick target slabs at $30 \mu \mathrm{~m}$ depth in water medium. The curves represent the frequency of total energy deposition by individual particles averaged over the total number of particles simulated. Different curves represent different ions traversing the target slab.

Delta-ray kinetic energy can be calculated, as discussed earlier, or it can be scored along with particle fluence in the FLUKA simulation. Energy fluence is scored by the number of electrons crossing a cylindrical boundary parallel and surrounding the ion track. Figure 14 displays the frequency of an electron with a corresponding kinetic energy crossing a 5 nm radius water cylinder, $1 \mu \mathrm{~m}$ long. The Ti-48 ions, having the highest charge and velocity, create more delta rays that can extend to higher kinetic energies. The maximum energy delta rays for each ion are described by the cut-off values, of each curve, seen in Figure 14.

Figure 14. Delta-ray production and their corresponding kinetic energy for ions having equal stopping powers of $100 \mathrm{keV} \mathrm{um}^{-1}$.

When velocity is equal, variations in delta-ray production depend only on the primary ion charge. Figure 15 describes the effect of effective charge on delta-ray production. Ions of different charge, but equal velocity, have different ranges in target media. The ions depicted in Figure 15 have sufficient velocity that stopping power and range do not vary significantly over target thickness.

Figure 15. Delta-ray production and their corresponding kinetic energy for equal velocity ions at $600 \mathrm{MeV} \mathrm{n}^{-1}$.

Looking back to the delta-ray distribution formula proposed by Katz (1967), delta-ray production can be calculated for any of the ions considered in this research. Figure 16 shows a comparison of the simulated data to Katz theory for delta-ray production from an $\mathrm{Si}-28$ ion at $164 \mathrm{MeV} \mathrm{n}^{-1}$. There is some deviation at energies below about 4 keV , and the FLUKA code does not track electrons below 1 keV . Part of the difference may be due to the fact that the FLUKA model is scoring electrons that have traversed at least 5 nm radially outward from the ion, while the Katz formula includes all electrons produced by the traversing ion. The curves do match for energies above $\sim 4 \mathrm{keV}$.

Figure 16. Delta-ray production for $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping power $\mathrm{Si}-28$ ion predicted by FLUKA simulation ( - ) and the Katz equation ( --- ).

The lower the electron kinetic energy, the more tortuous its track. Lower-energy electrons are also emitted at a larger angle to the ion path. These delta rays come off at nearly a 90-degree angle but do not follow straight paths. Higher-energy electrons are more forward directed, with straighter paths until they slow down.

To further investigate the necessary delta-ray buildup depth, ions were simulated to traverse a 1 mm thick water target. Figure 17 displays the mean energy deposited in 1 $\mu \mathrm{m}$ slabs at increasing depth. It is apparent that the energy deposited per micrometer by Ca-40 and Ti-48 ions never achieve the calculated stopping power of $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ in a 1 mm thick water target. In fact, the FLUKA-simulated LET without delta-ray loss were 94.26 and 98.35 for Ti-48 and $\mathrm{Ca}-40$, respectively, so there is some discrepancy between the calculation and Monte Carlo simulation. The Be-8 ion stops in the target and the C-

12 ion reaches a much higher stopping power, so neither are included to provide a clear view of the other ion LET values.

Figure 17. LET as a function of depth in a 1 mm thick water target. The stopping power of the ions were calculated to be $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ in water.

Realistically, the Ca-40 and Ti-48 ions do not deposit their maximum energy loss value within 1 mm of water because a small portion of their delta rays can travel a millimeter, or more, in water. Since the medium surrounding the target is a vacuum, the curves tail downwards at the exit face of the target because there is no back-scattering of delta rays. Exit stopping powers (following 1 mm of water) are listed in Table 5 for both ions of equal stopping power and separately, for ions of equal velocity. The Be-8 ion stops at about $300 \mu \mathrm{~m}$ depth in the target. The stopping power values in Table 5 describe the effect of the ion slowing down and increasing its LET as it penetrates matter.

Table 5. Calculated stopping power as the ion exits the 1 mm thick water target.

| Ion | $\mathrm{Be}-8$ | $\mathrm{C}-12$ | $\mathrm{O}-16$ | $\mathrm{Mg}-24$ | $\mathrm{Si}-28$ | $\mathrm{Ca}-40$ | $\mathrm{Ti}-48$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $100 \mathrm{keV} \mathrm{um}^{-1}$ ions | 0 | 216.21 | 117.84 | 103.11 | 101.55 | 100.14 | 100.01 |
| $600 \mathrm{MeV} \mathrm{n}^{-1}$ ions | 4.12 | 9.28 | 16.5 | 37.13 | 50.55 | 103.2 | 124.88 |

The increase in LET is primarily concentrated in the small core region surrounding the primary, and the only change in the penumbra is due to decreased velocity and effective charge. For this target thickness, the higher velocity ions are affected less, and the increase in dose is actually due to delta-ray buildup. The stopping power for equal velocity ions does not vary at the same rate, largely due to the ion charge, but also because of variations in the amount of energy being deposited by delta rays. Changing LET is incidental to laboratory experimentation so it is included in this study to promote a more realistic approach.

## Radial Dose Profiles

After discussing the characteristics of energy deposition and secondary electron generation longitudinally along the ion path, the next step is to analyze the dose deposited radially. To compare the FLUKA geometry with the amorphous track model, delta-ray equilibrium must be established. By setting the target slab at a depth dependent on the buildup depths described earlier, delta-ray equilibrium is satisfied. Unfortunately, as depth increases, the primary ion tends to scatter away from its initial trajectory. At $10 \mu \mathrm{~m}$ depth, a primary ion scattering over 5 nm radially (out of the innermost shell) represents more than a 0.0005 degree scatter. This is extremely small,
but creates errors in the radial dose results at small radii. To account for this, events are only scored when the ion leaves the rear of the 5 nm radius target shell (meaning it remained within that shell for its entire track). This method simulates the common experimental practice of requiring coincidence with an exit-detector pulse. The FLUKA USERBDX input option scores the forward fluence of particles crossing the downstream boundary for each cylindrical shell. Ions that exit shells other than the 5 nm radius must be subtracted from the radial dose analysis because they impart their core regions and penumbras in the wrong place. This process was applied to generate the data in Figure 18, so only the ions that actually exit out the rear of the 5 nm cylinder are scored. The radial dose profiles deposited by ions of $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ are presented in Figure 18 and extend over many orders of magnitude.

The trends are similar, and are difficult to distinguish on a log-log plot. The effects of increased radial distance are evident at large radii, greater than about $5 \mu \mathrm{~m}$. A $5 \mu \mathrm{~m}$ radius is also the approximate distance where delta-ray buildup and target thickness become significant factors. Scattering effects are more noticeable for the slower ions, although they require less delta-ray buildup depth. The dose profiles described above are at different depths, corresponding to the necessary buildup depth for the individual ion.

Figure 18. Dose as a function of radial distance away from the primary ion track for $100 \mathrm{keV} \mathrm{mm}^{-1}$ stopping power ions. Data points describe the dose in each cylindrical shell modeled in the FLUKA geometry. Target slab depth is located at the minimum depth required for delta-ray equilibrium corresponding to the velocity of each ion.

Radial dose ranges over many orders of magnitude, so an easier way to view the information is by the percent of the total dose that is deposited within a certain radial distance. Figure 19 displays the percent of total radial dose deposited vs. radial distance of predicted by the Chatterjee model (Chatterjee and Schaefer 1976) compared to that predicted in cylindrical shells modeled using the FLUKA code. These results represent ions with $100 \mathrm{keV} \mathrm{um}^{-1}$ stopping power.

The slower moving ions deposit more energy within small radii and less at large radii. Were the data to extend below 1 keV delta rays, the percent dose at 5 to 10 nm would probably be lower and more similar to the Chatterjee data. Those electrons may
have enough range to travel outside a 10 nm radius, reducing the core dose and depositing energy at larger radii. Most of the ions are not depositing $100 \%$ of their dose in the 1 micron slab, describing energy lost to delta rays escaping the target. This reduced dose is partly dependent on the depth of the target slab as described earlier in the section discussing delta-ray buildup. It also depends on the energy deposition trends previously discussed.

Figure 19. Percent radial dose as a function of radial distance away from the primary ion track of ions with equal stopping power of $100 \mathrm{keV}_{\mu \mathrm{m}}{ }^{-1}$ in water. Chatterjee data are presented for $\mathrm{Be}-8, \mathrm{Si}-28$, and $\mathrm{Ti}-48$ ions. For the FLUKA-simulated data, data points represent the percent of dose deposited within that cylindrical shell radius.

These dose profiles contain energy deposition spectra for several hundred thousand particle traversals through the same target orientation. The reason delta-ray
equilibrium is not established at large radii is because the highest energy delta rays require significant buildup depths relative to the amount of scattering undergone by the primary particle. Simulating radial dose for that depth would reduce the accuracy of measurements at small radii where dose is much more significant compared to the outer radii. The FLUKA trends are not the same as the Chatterjee trends, but they do appear to have about the same maximum penumbra radii.

The radial dose plots in Figures 18 and 19 display data at a point within the target delta-ray equilibrium exists within the penumbra radius determined by the Chatterjee approach. Increases in stopping power are negligible, but there has been adequate depth for delta ray buildup within the $5 \mu \mathrm{~m}$ radius. The higher velocity ions have been allowed thicker buildup targets because their LET and angular scatter are affected less.

Estimating probabilities for DNA target hits is not possible to simulate with this model, due to the delta-ray energy cutoff in the FLUKA code. However, dose deposited across the cell, and into neighboring cells, can be modeled effectively. Figure 20 presents the radial dose on a narrower scale - the radial dose at 50 nm to $5 \mu \mathrm{~m}$ for 100 $\mathrm{keV} \mu \mathrm{m}^{-1}$ ions. Electrons with kinetic energies below 1 keV do not travel much farther than 50 nm in water, so their absence in the FLUKA simulation should not skew the data presented in this plot. Were the ion to cross the middle of a cell nucleus, the radial distance scale displayed in Figure 20 depicts the penumbra dose across that cell nucleus. The lighter ions deposit the larger dose across that distance.

Figure 20. Dose as a function of radial distance away from the primary ion track. Ions displayed have equal stopping power of $100 \mathrm{keV}_{\mu \mathrm{m}}{ }^{-1}$ in water. Data points represent the dose deposited in cylindrical shells surrounding the primary ion path for the C-12 and Ti-48 ions.

The trend in Figure 20 describes how ions of equal stopping power, but different velocity, transition toward a region where the radial dose is equal. Dose at 50 nm radii is significantly different, while dose a $5 \mu \mathrm{~m}$ is more similar. The doses for the lighter ions tail off, while the penumbrae of the heavier (and faster) ions extend outward much farther, but at very low dose - a region describing rare, but large radial distance effects. Within a $10 \mu \mathrm{~m}$ diameter is truly the region of interest for this dose model. Inside 0.05 $\mu \mathrm{m}$, the dose is dominated by the primary ion and its short-range delta rays, while outside $10 \mu \mathrm{~m}$, events are rare and diffuse.

Figure 21 describes the effect of delta-ray buildup in the radial dose model.
High-energy electrons are very forward directed with relatively straight paths, but the
chance of them re-entering the narrow shell regions is very small. Correspondingly, delta-ray buildup only affects the larger radial volumes.

Figure 21. Percent radial dose as a function of radial distance away from the primary ion track for $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping power $\mathrm{Ca}-40$ ions at increasing depth in water. Data points represent the dose deposited in cylindrical shells surrounding the primary ion path. Separate curves represent different target depths inside a water medium.

The trend in Figure 21 emphasizes that delta-ray buildup is primarily an effect measured above $10 \mu \mathrm{~m}$ away from the ion track, describing regions outside a cell nucleus diameter. The inner cylindrical volumes are so small, it is rare for a scattered particle to come from outside and deposit any significant amount of energy. As target depth increases, the primary ions tends to scatter outside of the 5 nm radius shell. These scattering events must be subtracted from the FLUKA data and more primary particles must be simulated to achieve adequate statistics.

Ions of equal velocity exhibit the same radial dose trends, only at different magnitudes, due only to the effect of $Z^{2}$. In Figure 22, Ti-48 ion dose is seen beyond $1000 \mu \mathrm{~m}$, and describes a statistical effect due to the larger number of delta rays that are produced.

Figure 22. Dose as a function of radial distance away from the primary ion track for equal velocity ions at $600 \mathrm{MeV} \mathrm{n}^{-1}$. Data points represent the dose deposited in cylindrical shells surrounding the primary ion path.

Figure 23 displays the percent of the total dose deposited within a radial distance by ions with equal velocity. The trends are the same because the ions produce delta rays with the same kinetic energies. Therefore, the same percentage of an ion dose is deposited along the radial distance, regardless of charge.

Figure 23. Percent radial dose as a function of radial distance away from the primary ion track for equal velocity ions at $600 \mathrm{MeV} \mathrm{n}^{-1}$. Data points represent the dose deposited in cylindrical shells surrounding the primary ion path.

To keep this study focused on relative damaging ability, particle fluence is also scored for electrons crossing from inner shell regions to outer regions. The trend is seen in Figures 24, 25, and 26 that the low-energy electrons stop within smaller radii because they have shorter range. High-energy delta rays do not create enough low-energy delta rays to maintain the energy spectrum.

Figure 24 displays the number of delta rays traveling outward from the primary track at increasing radii. The lower-energy electrons obviously do not travel as far, as seen by the decreasing trend at lower energies. This spectrum is similar for the different ions, and only $\mathrm{Si}-28$ is depicted here. $\mathrm{Ca}-40$ and Ti-48 ions produce higher-energy electrons that travel farther than the $50 \mu \mathrm{~m}$ radius seen here.

Figure 24. Frequence of delta rays crossing the surface of shell detectors with increasing radii for the $\mathrm{Si}-28$ ion with $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping power. The shell radii have dimensions of microns.

Taking the same measurements, four ions are plotted in relation to each other at 75 nm and 250 nm radii in Figures 25 and 26. Delta-ray abundance for energies below 2 keV is significantly reduced between 75 and 250 nm , signifying the extent of their range. Very high-energy delta rays of a few MeV are produced by the Ti-48 ion. Those delta rays exhibit less reduction in abundance at these small radii compared to those produced by a slower-moving ion. As delta rays traverse the water medium, they slow down and can generate small populations of tertiary delta rays. The $\mathrm{Be}-8$ ion data show that there remains are very small population of delta rays between 15 and 20 keV . This trend also appears for the $\mathrm{O}-16$ ion above about 80 keV .

Figure 25. Frequence of delta rays crossing the shell detector at 75 nm radius for ions with $100 \mathrm{keV} \mathrm{mm}^{-1}$ stopping powers. Lower-velocity ions produce delta rays with smaller kinetic energy and range.

Figure 26. Frequence of delta rays crossing the shell detector at 250 nm for ions with $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers. Lower-velocity ions produce delta rays with smaller kinetic energy and range.

Table 6 displays the dose deposited by delta rays in cylindrical shells for radii
from outside $1 \mu \mathrm{~m}$ up to 10 mm . The shell with a $5 \mu \mathrm{~m}$ radius contains the dose
between 1 and $5 \mu \mathrm{~m}$. For ions with equal stopping powers, higher velocity is shown to produce higher doses at large radii.

Table 6. Penumbra dose for ions with $100 \mathrm{keV} \mathrm{\mu m}^{-1}$ stopping powers scored in cylindrical shells of different radii outside $1 \mu \mathrm{~m}$ radius. The maximum dose for each radial distance is displayed in bold font.

| Radial Distance $(\mu \mathrm{m})$ | 10000 | 1000 | 100 | 50 | 10 | 5 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |

Lower velocity ions produce narrower penumbrae. Table 7 displays dose deposited in cylindrical shells for radii inside of $1 \mu \mathrm{~m}$. All ions impart significantly higher doses in the smaller shell volumes. Table 7 shows that the $\mathrm{C}-12$ ion dominates the radial dose within $1 \mu \mathrm{~m}$ radii. The $\mathrm{Be}-8$ ion is experiencing the end of its track, so secondary electrons have very small ranges. The 5 nm radius shell absorbs a smaller dose from the $\mathrm{Be}-8$ ion compared to the $\mathrm{C}-12$ ion, describing an inconsistency between the FLUKA code calculations compared with the Bethe-Bloch approach for energy loss as well as the Chatterjee trends. Excluding the Be-8 ion, for ions of equal stopping power, radial dose decreases with increasing primary ion velocity inside a $1 \mu \mathrm{~m}$ radius.

Table 7. Penumbra dose for ions with $100 \mathrm{keV}_{\mu \mathrm{m}}{ }^{-1}$ stopping powers scored in cylindrical shells of different radii inside $1 \mu \mathrm{~m}$ radius. The maximum dose for each radial distance is displayed in bold font.

| Radial Distance ( $\mu \mathrm{m}$ ) | 1 | 0.75 | 0.5 | 0.3 | 0.15 | 0.1 | 0.05 | 0.025 | 0.01 | 0.005 |

Without knowing actual target hits, it is difficult to relate radial dose information to realistic damage. The delta-ray kinetic-energy spectra were determined to follow similar trends, and high-energy events are very unlikely. As radial distance increases, the dominating penumbra dose shifts toward the higher velocity ions. This dose value is largely dependent on the velocity of the ion, while the full target geometry plays a part as well. $\mathrm{C}-12$ ions dominate the radial dose within a $1 \mu \mathrm{~m}$ radius.

The FLUKA-simulated radial dose model is effective for understanding the general trends of delta rays and describes the influence of primary ion charge and velocity. Unfortunately, it does not provide enough information for determining physical damage to biologically relevant targets, especially for single-ion traversals. The number of delta rays crossing each cylindrical region surrounding the ion trajectory and the corresponding energy that they deposit determine the ionizations that will be imparted to sensitive targets. Of the radial dose trends discussed here, several challenges to the accuracy of the simulation have arisen, including primary ion scatter, delta-ray buildup, and stopping power increasing across target depth. To address these shortfalls, additional target geometries must be simulated.

## Mesh Geometry Analysis

To effectively demonstrate how a track structure realistically affects nearby targets, a set geometry must be utilized to provide microdosimetry information. Target dose and hits can be determined by simulating a water geometry housing many adjacent, small detectors. The mesh cube geometry consists of 1 million cube-shaped voxels with edges of $10 \mu \mathrm{~m}$ that make up a large cube having edges of 1 mm . The mesh cylinder is housed inside the volume of one $10 \mu \mathrm{~m}$ voxel. It provides dosimetry analysis for one million (nearly) cube-shaped voxels with edges of 10 nm that make up a cylinder with a $5 \mu \mathrm{~m}$ radius and $10 \mu \mathrm{~m}$ length. The goal is to establish cell-damage probabilities based on dose and particle fluence accounting for each individual target. Measurements include the buildup of secondary particles, primary ion scatter, and to a lesser extent fragmentation. Radial dosimetry around the ion track can also be performed. The geometry is small enough not to lose site of the track structure approach to still be able to discriminate the different energy deposition spectra and their spatial distributions.

The FLUKA code simulates the primary ion traversing the middle of a voxel contained near the center of the mesh geometry. The code records energy deposited and particle fluence for each voxel following each event. This particle is simulated through the same point and axis 200,000 times to improve the statistics and develop trends for each ion and irradiation scenario. Dose and particle fluence events for each voxel are cumulative over the 200,000 particle traversals and the resulting output data are presented as total dose or fluence divided by the 200,000 primary particles simulated. As trends are established for each ion, results can be compared by normalizing values
with respect to the total energy they deposit in the target per primary ion. In order to establish damaging ability of these ions, the damage to surrounding targets is analyzed with respect to dose and particle traversals. Figure 27 describes the population of voxels, within the entire $1 \mathrm{~mm}^{3}$ target, that receive a dose corresponding to the abscissa value.

Average Dose / Voxel (Gy)
Figure 27. Population of $1,000 \mu \mathrm{~m}^{3}$ targets receiving a dose in the mesh cube geometry by ions with $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers. Dose is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primary-ion events produce many zero dose values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

Dose represents the energy deposited by secondary electrons averaged over 200,000 primary ion traversals. For single primary ion traversals, most voxels are unaffected, so the final average value includes these zero values. Therefore, the dose
appears orders of magnitude less than what is actually experienced by a voxel when it is hit. The very high dose values signify the targets that are traversed by the primary ion. For targets not traversed by the primary ion, this plot displays a more significant electron dose coming from the higher velocity ions. Multiple high-dose points represent scattering of the primary particle. The lowest dose events that affect a very high number of targets represent targets that receive zero (or very near to zero) dose. This means that zero, or one, electrons interacted in this voxel following 200,000 simulations. These voxels are assumed to be un-hit targets. This plot was generated from a histogram of target events, described by the data located in Appendix B. The lowest dose bin ranges from $0-1 \times 10^{-12}$ and contains the zero dose voxels. Excluding primary ion tracks, the Ti-48 ion affects the most targets with the highest doses. Ca-40 and Ti-48 are seen to affect the largest number of targets, with very similar trends. The high-dose data points are dispersed for $\mathrm{C}-12$ due to the large amount of scattering it experiences when traversing 1 mm of water. The higher-velocity ions scatter less, and therefore, display only one, or a few, high dose data points. Decreasing $Z$ and velocity decreases the abundance and range of the delta rays, so fewer targets are affected. To better visualize the trend, Figure 28 displays the effects of ions with equal velocity. As already established, they have very similar trends, with a simple increase in magnitude due to charge. In both plots, there are more un-hit targets for lower Z ion traversals, signifying decreased delta-ray production.

There is a clear distinction of 100 targets receiving primary ion doses seen in Figure 28 that is not as apparent for the equal stopping power ions in Figure 27. As
detailed in Appendix B, the highest energy events do sum to 100 for each different ion, describing that the 1 mm thick target is 100 voxels thick. In Figure 28, there are two data points representing primary particle dose from Ti-48. This is an effect of the binning structure, as the edge of the high dose bin lies very near the corresponding primary track dose for the ion. For equal velocity ions, the number of targets affected at any dose is proportional to $Z^{2}$. For single primary ion traversals, most voxels are unaffected, so the final average value includes these zero values. Therefore, the dose appears orders of magnitude less than what is actually experienced by a hit voxel.

Figure 28. Population of $1,000 \mu \mathrm{~m}^{3}$ targets receiving a dose in the mesh cube geometry by ions with $600 \mathrm{MeV} \mathrm{n}^{-1}$ velocities. Dose is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primary-ion events produce many zero dose values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

Figures 29 and 30 display a similar histogram, except the targets are affected by electron fluence, instead of dose. Similar to the dose measurements in Figures 27 and 28 , the particle fluence values are averaged over the 200,000 primary ions simulated. Targets traversed by the primary ion experience greater-than one particle traversal due to the number of delta rays produced by the ion. The Be-8 ion, having the slowest velocity in Figure 29, affects significantly fewer targets since it has such a small penumbra. There are three data points signifying primary tracks, where particle fluence is greaterthan one. The Be- 8 peak describes the few delta-ray events that escape the volume of the $10 \mu \mathrm{~m}$ thick voxels located along the primary particle axis. As velocity increases, the number of delta rays escaping those central voxels increases creating a broader data curve. The Ca-40 and Ti-48 ions have a similar profile, suggesting their penumbras envelop roughly the same dimensions for this particular target geometry. The Ca-40 ion, with lower velocity, still manages to create energetic-enough delta rays to affect most targets inside this geometry.

Figure 29. Population of $1,000 \mu \mathrm{~m}^{3}$ targets affected by traversing electrons in the mesh cube geometry by ions with $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers. Fluence is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primary-ion events produce many zero fluence values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

The ions of equal velocity all produce a similarly-shaped curve that is proportional to $Z^{2}$. There is a peak of $\sim 20,000$ targets affected by $1 \mathrm{E}-5$ to $1 \mathrm{E}-3$ electrons per primary ion. This 20,000 target peak is also seen in the dose plot. Dose-depth and radial dose profiles can also be taken from these data although radial dose is only as narrow as the $10 \mu \mathrm{~m}$ voxel. Figures 27 and 29 present similar trends, indicating a correlation between the energy deposited and delta-ray fluence. This similarity is also present for Figures 28 and 30.

Figure 30. Population of $1,000 \mu^{3}$ targets affected by traversing electrons in the mesh cube geometry by ions with $600 \mathrm{MeV} \mathrm{n}^{-1}$ velocities. Fluence is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primary-ion events produce many zero fluence values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

Figures 28 and 30 showed that the delta-ray penumbra depends only on $Z^{2}$ for ions of equal, $600 \mathrm{MeV} \mathrm{n}^{-1}$, velocity. Therefore, it can be deduced that the shapes of the curves in Figures 27 and 29 are based on ion velocity and those curves would be the same for any ion having the same velocity; only the magnitude of each point would vary by $\mathrm{Z}^{2}$.

The next step toward an estimate of damaging ability is the correlation of dose and particle fluence for each target. Figure 31 displays the electron fluence that deposits a certain dose per voxel averaged over 200,000 primary ion simulations. The linear
slope that creates the backbone of each series is a reflection of the similar shapes of the dose curves in Figures 27 and 29, and of the particle fluence curves in Figures 28 and 30. The ions represented in Figure 31 are Ti-48, O-16, and Be-8, having equal stopping power at the target's entrance surface. Only three ions were shown for visual clarity between the data points. Figure 32 is the same as Figure 31, but includes the $\mathrm{Si}-28$ ion events. For both Figures 30 and 31, the primary ion dose is depicted in the top right where dose is highest and there is greater-than 1 particle crossing per target. The large data section of the plot represents the delta-ray penumbra. The Be- 8 extends to a higher dose because it experiences its Bragg peak within the 1 mm cube. It also has the lowest incidence of particle traversals and at a low dose. There are very few, high-dose, data points from the Be-8 ion that suggest unlikely events where the primary ion scatters significantly and comes to a stop in a rare voxel.

Figure 31. The electron fluence corresponding to a given dose for individual $1,000 \mu \mathrm{~m}^{3}$ targets inside the cube mesh geometry for Be-8, O-16, and Ti-48 ions with $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers. Fluence vs. dose is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primaryion events produce many zero dose and fluence values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

In Figure 32, the Si-28 ion appears to have the most significant penumbra, because it covers the largest area. The Ti-48 ion actually has more overlap of data points, but it is not described well by this figure. Referring to the particle fluence histogram in Appendix B, the Ti-48 ion affects all targets in the cube.

Figure 32. The electron fluence corresponding to a given dose for individual $1,000 \mu \mathrm{~m}^{3}$ targets inside the cube mesh geometry for $\mathrm{Be}-8, \mathrm{O}-16, \mathrm{Si}-28$, and Ti-48 ions with 100 $\mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers. Fluence vs. dose is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primary-ion events produce many zero dose and fluence values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

The ions exhibited different shapes and magnitudes for Figures 31 and 32.
Figure 33 displays the results for ions of equal velocity. The ions represented are Ti-48, $\mathrm{O}-16$, and $\mathrm{Be}-8$ at $600 \mathrm{MeV} \mathrm{n}^{-1}$. The trends carry shape similarities, and there's more overlap for higher Z ions, describing a higher magnitude of dose and particle fluence for the Ti-48. In Figure 33, the Be-8 ion data cover the largest area, while the Ti-48 ion covers the smallest. The Ti-48 ion affected all targets inside the mesh cube geometry, so
the particle fluence and dose values continued to add up, unlike the $\mathrm{Be}-8$ ion that affected few targets.

Figure 33. The electron fluence corresponding to a given dose for individual $1,000 ~ \mu \mathrm{~m}^{3}$ targets inside the cube mesh geometry for $\mathrm{Be}-8, \mathrm{O}-16$, and $\mathrm{Ti}-48$ ions with $600 \mathrm{MeV} \mathrm{n}^{-1}$ velocities. Fluence vs. dose is presented as a trend that is averaged over the events produced by 200,000 primary particles traversing the geometry. Single primary-ion events produce many zero dose and fluence values making the average values orders of magnitude lower. Individual primary ion events would be seen as only a few, random, data points.

Table 8 was created from the mesh cube data presented in Figures 27, 29, 31, 32.
Based on each ion velocity, the total dose deposited in the cube varies significantly as shown in Figure 17 due to the change in stopping powers leading to higher dose from the
slower ions. The Be-8 ion imparts the least dose, because it stops near the $300 \mu \mathrm{~m}$ depth. The $\mathrm{O}-16, \mathrm{Mg}-24, \mathrm{Si}-28$, and $\mathrm{Ti}-48$ ions all deliver about the same percent of dose by delta rays. Unlike the $\mathrm{Be}-8$ and C-12 ions, the higher velocity ions are not increasing significantly in stopping power across the 1 mm thick cube. The $\mathrm{Ca}-40$ and Ti-48 ions are exhibiting delta-ray loss, by imparting slightly lower-electron doses than the doses of the $\mathrm{O}-16, \mathrm{Mg}-24$, and $\mathrm{Si}-28$ ions. The $\mathrm{O}-16, \mathrm{Mg}-24$, and $\mathrm{Si}-28$ ions also impart a higher-electron dose to far fewer targets than the $\mathrm{Ca}-40$ and $\mathrm{Ti}-48$ ions.

Similarities in electron dose values suggest that the ions actually impart the same LET values through secondary electron production. Velocity and target geometry have a strong influence on obtaining consistent dosimetry readings.

Table 8. Dose characteristics within mesh cube geometry for ions having $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers. Data describe the number of targets affected by variations in the deltaray penumbra created by ions with different velocities.

| $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ | $\mathrm{Be}-8$ | $\mathrm{C}-12$ | $\mathrm{O}-16$ | $\mathrm{Mg}-24$ | $\mathrm{Si}-28$ | $\mathrm{Ca}-40$ | $\mathrm{Ti}-48$ |

The damaging ability of the $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ ions was determined from the population of targets that receive dose by secondary-electron traversals. Table 9 presents a summation of the product of dose and number of targets affected for each curve. This information is described by taking the area under each curve in Figures 27 and 29. The analysis is performed, separately, for both the dose plot in Figure 27 and
the particle traversal plot in Figure 29. Different radiation types are commonly compared by their damaging ability relative to a reference radiation to establish RBE values. The results of this research are normalized to the $\mathrm{Si}-28$ ion value because it represents a mid-point value for charge and velocity. Damaging ability is summed from the data calculated by the FLUKA code and presented in Table 9. The primary ion track for each simulation includes significant scattering effects and increases in stopping power for lower-velocity ions. For the higher-dose values in Figures 27 and 29, the lower-velocity ions display a scattering of data points. The data presented in Table 9 exclude dose and electron fluence data for the voxels located in the center of the target that are traversed by the primary ions. The data are not presented in conventional dosimetry terms, because each dose and particle traversal data point is multiplied by its frequency. Summing each target dose does not yield the total dose for the mesh cube.

Table 9. Voxel dose and particle traversals are summed, separately, from data in Figures 27 and 29 to establish a value for damage imparted to targets located more than $5 \mu \mathrm{~m}$ from the primary ion track.

|  | Cumulative Dose Events | $\begin{gathered} \text { Relative to } \\ \text { Si-28 } \end{gathered}$ | Cumulative Particle <br> Fluence Events | Relative to Si-28 |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{Be}-8$ | $5.56 \mathrm{E}-05$ | $2.59 \mathrm{E}-05$ | $2.86 \mathrm{E}-03$ | $1.46 \mathrm{E}-06$ |
| C-12 | 1.0290 | 0.4792 | 146.69 | 0.0751 |
| O-16 | 1.2457 | 0.5802 | 519.75 | 0.2660 |
| Mg-24 | 1.9839 | 0.9240 | 1537.69 | 0.7871 |
| Si-28 | 2.1470 | 1.0 | 1953.68 | 1.0 |
| Ca-40 | 2.1603 | 1.0062 | 2384.28 | 1.2204 |
| Ti-48 | 2.0454 | 0.9527 | 2386.41 | 1.2215 |

The Ti-48 ion produces the most targets affected for the mesh cube geometry. The dose imparted by the Ti-48 ion penumbra is less than that for the $\mathrm{Ca}-40$ and $\mathrm{Si}-28$ ions because of delta rays escaping the target. Information presented in Table 9 gives a relation for penumbra effects at radial distances greater than the core axis of $5 \mu \mathrm{~m}$ voxels at the center of the mesh geometry. The cylindrical mesh geometry provides dosimetry inside the $5 \mu \mathrm{~m}$ radius.

The cylindrical mesh, having radius of $5 \mu \mathrm{~m}$ and length of $10 \mu \mathrm{~m}$, contains 1 million voxels with $1000 \mathrm{~nm}^{3}$ volumes, simulating DNA-sized targets within a cell nucleus. A simulation of 200,000 primary ions was performed with the FLUKA code only for ions of equal stopping power. The dose and particle fluence were calculated for each voxel. Figure 34 displays radial dose across the mesh cylinder, similar to the earlier models in this study. Agreeing with the cylindrical shell simulation, C-12 ions deliver the highest dose up to a $2 \mu \mathrm{~m}$ radius, where $\mathrm{O}-16$ ions begin to impart higher dose due to a slighter larger penumbra. The Be- 8 ion penumbra drops off at $4 \mu \mathrm{~m}$, characterizing the outer reaches of its penumbra. The radial distance scale represents penumbra data within a $5 \mu \mathrm{~m}$ radius down to the primary track, detailing track structure within a cell nucleus-sized volume.

Figure 34. Dose as a function of radial distance away from the primary ion track inside the cylindrical mesh geometry. Data points represent FLUKA calculations for delta rays created by ions of equal $100 \mathrm{keV} \mathrm{mm}^{-1}$ stopping powers traversing a $10 \mu \mathrm{~m}$ thick water target. Dose values are averaged over 200,000 primary particles traversing the geometry.

Figure 35 displays the mesh cylinder data for $\mathrm{C}-12$ and Ti-48 ions in reference to the Chatterjee calculation. The trends are quite similar, but there is definitely a difference in magnitude between the two approaches. A larger discrepancy in magnitude appears for the Ti-48 ion, as opposed to the C-12 ion data. This discrepancy is most likely due to the effect of delta-ray buildup, as the higher-velocity Ti-40 ion requires larger buildup depth.

Figure 35. Dose as a function of radial distance away from the primary ion track inside the cylindrical mesh geometry presented with Chatterjee data. Data points represent FLUKA calculations for delta rays created by ions of equal $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers traversing a $10 \mu \mathrm{~m}$ thick water target. Data lines represent Chatterjee calculation for the same ions. For FLUKA data, dose and particle fluence values are averaged over 200,000 primary particles traversing the geometry.

Figures 36 and 37 display data for the dose and particle fluence, for individual voxels, imparted by delta rays produced within the mesh cylinder. Dose and particle fluence is averaged over 200,000 primary particle simulations. The Be-8 ion track structure is well contained within the small geometry of $10 \mu \mathrm{~m}$, which is why the curve in Figure 36 presents such a broad spectrum of events. As velocity increases, and deltaray ranges increase, the trends become more similar, as more targets are affected by a
higher-energy delta ray spectrum. The trends described in Figures 36 and 37 exhibit a lower occurrence of events at low-dose for lower velocity ions and a higher occurrence of events at higher-dose. The primary ion track extended over a depth of $10 \mu \mathrm{~m}$, and voxels are 10 nm thick. Therefore, the number of voxels receiving the core dose was 1,000 and is reflected by the plateau data in Figures 36 and 37 . There is a scattering of data around the $10-100$ Gy per target and 1E-4 to 2E-2 electrons per target area. These data represent primary ion scattering events away from the beam axis that deliver a higher dose to the surrounding targets. There is less scattering for the higher-velocity ions.

Figure 36. Population of $1000 \mathrm{~nm}^{3}$ targets experiencing delta-ray dose inside the cylindrical mesh geometry by ions with $100 \mathrm{keV} \mathrm{mm}^{-1}$ stopping power. Dose values are averaged over 200,000 primary particles traversing the geometry. The large change in shape of the Be-8 ion data trend explains the effect of events that deposit zero dose in some voxels.

The shape of the curves in Figures 36 and 37 is similar, as seen earlier in the larger mesh geometry. However, there is a slight deviation in the peak regions between Figures 36 and 37. The Be-8 and C-12 ions appear to deviate more than the other ions.

The dose per voxel can be divided by the electron fluence traversing that voxel, and describes differences in the approximate stopping powers of delta rays produced by different ions. As shown in Figure 38, the higher-velocity ions generate faster electrons, having lower-stopping power, so there are more events on the low end of the spectrum.

Average Electron Fluence / Voxel (electrons / $100 \mathbf{n m}^{2}$ )
Figure 37. Population of $1000 \mathrm{~nm}^{3}$ targets experiencing delta-ray fluence inside the cylindrical mesh geometry by ions with $100 \mathrm{keV}_{\mu \mathrm{m}}{ }^{-1}$ stopping power. Fluence values are averaged over 200,000 primary particles traversing the geometry. The large change in shape of the Be-8 ion data trend explains the effect of events that deposit zero dose in some voxels.

This analysis can be performed for this geometry because there is minimal ion scattering, and nearly all targets are traversed by delta rays. The $\mathrm{Be}-8$ ion delta rays deliver higher dose on a per-particle basis. There is a maximum cut-off value experienced by each ion, except for $\mathrm{Be}-8$, in Figure 38. This effect describes the range of possible dose values deposited by a delta ray that traverses the voxel targets.

Figure 38. Dose per electron fluence across the population of $1000 \mathrm{~nm}^{3}$ targets in the cylindrical mesh geometry by ions with $100 \mathrm{keV}_{\mu \mathrm{m}^{-1}}$ stopping power. Dose and fluence values are averaged over 200,000 primary particles traversing the geometry. Be8 ion abscissa values past $\sim 3.5 \mathrm{E} 4$ are attributed to primary ion scatter so the data is cut off.

The higher events exhibited by the Be-8 ion describe scattering of the primary ion into voxels outside of the beam centerline and are not included in the damage
calculation. Higher-velocity ions produce a larger number of delta rays that impart larger particle fluence per target, shown in Figure 37. The very small dose per fluence values experienced by the Be-8 ion describe the influence of un-hit voxels following individual primary ion events. These zero values are averaged into the total for each voxel. Smaller delta-ray fluence, in addition to increased delta-ray stopping power, result in the dominating C-12 ion curve in Figure 38.

The lower-velocity ions exhibit delta rays with a higher stopping power within a cell nuclei-sized volume. Similar to the analysis creating the data in Table 9, Table 10 presents damaging ability as the area under the curve for Figures 36, 37, and 38. The damage value is calculated by multiplying the abscissa value by the number of targets affected in Figures 36, 37, and 38. That information is summed into the data in Table 10 and displayed as the product of the number of targets affected multiplied by the dose, particle fluence, or dose per electron fluence per target in the cylindrical mesh geometry.

Table 10. Damaging events in the cylindrical mesh target are described as the total product of dose, particle traversals, and dose per electron fluence multiplied by the population affected. Ions have stopping powers of $100 \mathrm{keV} \mu \mathrm{m}^{-1}$.

|  | Cumulative Dose Events | Relative to Si-28 | Cumulative Particle Fluence Events | $\begin{aligned} & \text { Relative } \\ & \text { to } \mathrm{Si}-28 \end{aligned}$ | Cumulative Dose/Electron Fluence Events | $\begin{aligned} & \text { Relative } \\ & \text { to Si-28 } \end{aligned}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Be-8 | $7.674 \mathrm{E}+05$ | 0.955 | 48.736 | 0.928 | $3.949 \mathrm{E}+09$ | 1.787 |
| C-12 | $1.072 \mathrm{E}+06$ | 1.335 | 71.570 | 1.363 | $2.656 \mathrm{E}+09$ | 1.202 |
| 0-16 | $9.646 \mathrm{E}+05$ | 1.201 | 64.678 | 1.232 | $2.382 \mathrm{E}+09$ | 1.078 |
| Mg-24 | $8.416 \mathrm{E}+05$ | 1.048 | 56.045 | 1.067 | $2.234 \mathrm{E}+09$ | 1.011 |

| Ca-40 | $7.008 \mathrm{E}+05$ | 0.872 | 46.402 | 0.884 | $2.167 \mathrm{E}+09$ | 0.980 |
| Ti-48 | $6.393 \mathrm{E}+05$ | 0.796 | 41.644 | 0.793 | $2.151 \mathrm{E}+09$ | 0.973 |

To assess the damage imparted, Table 10 presents the product of interaction events with the number of targets experiencing those events. C-12 delivers the highest dose and delta-ray fluence for the cylindrical mesh. Ti-48 delivers the lowest values, signifying a lower amount of damage within this intercellular volume. Table 9 showed that for radial distances beyond $5 \mu \mathrm{~m}, \mathrm{Ca}-40$ scores the highest damage value for dose and Ti-48 scores larger delta-ray fluence. This is a direct example of the electron stopping power being higher for the delta rays produced by the $\mathrm{Ca}-40$ ion, compared with the Ti-48 ion delta rays. In this cylindrical mesh, the $\mathrm{Be}-8$ ion creates delta rays with the highest stopping power. Table 11 averages the values from the two different mesh geometries to account for both inner and outer penumbra damaging effects. Data are displayed relative to the $\mathrm{Si}-28$ value in each category.

Table 11. Damaging events compared across cylindrical and cubic geometries.

| Ion | Cumulative Dose Events <br> Relative to Si-28 <br> $<10 \mu \mathrm{~m}$ |  | $>10 \mu \mathrm{~m}$ |  | Cumulative Particle Fluence <br> Events Relative to Si-28 |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Average | $<10 \mu \mathrm{~m}$ | $>10 \mu \mathrm{~m}$ | Average |  |  |

The mesh cube geometry is described as intracellular and contained outside of a $5 \mu \mathrm{~m}$ radius from the primary particle axis. The cylindrical geometry is described as intercellular and contained within a $5 \mu \mathrm{~m}$ radius. The combination of the two
geometries is meant to account for the high-energy density near the ion path as well as the large number of cells, far from the primary ion, that are affected. While $\mathrm{C}-12$ and O 16 were highly damaging at small radii, the large number of targets affected by the Ca40 and Ti-48 ions outweighs as a more significant factor. Damaging ability is seen to depend largely on the target volume of interest because velocity significantly determines where the energy is deposited. A larger number of cells are affected for higher-velocity ions, but the dose per delta ray is higher for lower-velocity ions. The data do show that the significantly high velocity of Ti-48 causes energy loss outside the target. Those delta rays have higher kinetic energy and, therefore, lower stopping power. Were the study to include targets outside of the 1 mm mesh cube, then the Ti-48 damaging effects would increase. This study may also indicate that kinetic energy in the range of a few hundred $\mathrm{MeV} \mathrm{n}^{-1}$ is significant to the volumes of interest for biological damage. This is also the most abundant velocity for GCR.

The relative damaging ability for the different ions has been described by two different microdosimetric studies for targets inside and outside the scale of a cell nucleus. Damage is due to the energy deposition of the secondary electrons surrounding the primary ion path. Ion kinetic energy directly influences the localization of dose. A slower-traveling ion does more damage at small radii, while a faster ion spreads its dose to larger distances. The data show that the $\mathrm{Be}-8$ ion $\left(6.8 \mathrm{MeV} \mathrm{n}^{-1}\right)$ isolates its dose to very narrow radii within about $1 \mu \mathrm{~m}$. The $\mathrm{C}-12$ ion $\left(18.5 \mathrm{MeV} \mathrm{n}^{-1}\right)$ proves to be the most effective velocity for concentrating its dose across about $5 \mu \mathrm{~m}$ radii, or the size of a cell nucleus. It is very helpful to reference the analysis of ions at equal velocity. It can
be concluded that the track structure of any ion at equal velocity will deliver the same spectrum of delta rays to a cell-sized volume, while the magnitude of dose depends only on $Z^{2}$. This conclusion does not hold for ions whose stopping power varies significantly over the target thickness.

Seven different ions, each at a different velocity were studied, and it has been determined that the spatial distribution of dose is dependent upon the primary ion velocity. The magnitude of the dose is dependent upon the primary ion charge. The next step in furthering this study would be to establish a normalized value for damage based upon the existing data, and removing the influence of each ion charge by dividing out $Z^{2}$. This normalized factor would then be established for each velocity (comparable to $\mathrm{MeV}{ }^{-1}$ ) used in the study. $\mathrm{Z}^{2}$ could be incorporated back into those velocities to provide damage factors for each ion and each seven different velocities.

Realistically, this information would only apply to ions whose stopping power do not vary significantly across the target. As long as the damaging effects are consistent with that produced in the equal velocity approach used in this study, then a normalized value for damaging ability could be developed for each velocity of interest. Ion charge could be simply incorporated by multiplying by $\mathrm{Z}^{2}$.

The decision for which ion imparts more damage relative to another comes down to the definition of damage. Considering GCR, genetic mutations created by mis- or unrepaired DNA, are the primary focus. If a cell is killed by a particle track in this low dose-rate environment, then it cannot go on to form a cancer. The region within a $5 \mu \mathrm{~m}$ radius has been described as one cell nucleus. The $\mathrm{Be}-8, \mathrm{C}-12$, and $\mathrm{O}-16$ ions contained
their damage primarily within this region, meaning the dose deposited on DNA strand sized targets would be higher. However, for a $1 \mathrm{~mm}^{3}$ target, their effects are only dominant for $\sim 100$ cells compared to $\mathrm{Si}-28, \mathrm{Ca}-40$, and $\mathrm{Ti}-48$ ions that affect far more cells. The other 999,900 cell nuclei will be more affected by the delta rays from a higher velocity ion. Therefore, emphasis must be placed on the number of cells receiving the largest number of particle traversals. Realistically, the Ti-48 affects many more cells, influencing its damaging ability outside the target volumes simulated in this research. Damaging ability is scenario specific and largely a factor of ion velocity and charge.

## CHAPTER V

## CONCLUSION

The biological risks of heavy ions encompass a broad field of research involving characterizing the space radiation field, shielding effects, track structure, biological damage, and repair mechanisms. Many factors determine how a HZE ion will interact with and change the mammalian cell that it traverses. This dissertation provided a review of these topics and focused on an in-depth study of track structure. The spatial distribution of energy deposition was determined by simulating biologically-similar target traversals by an ion and its secondary particles. Emphasis was placed on ion charge and velocity by keeping the targets of interest to a small scale. This approach helped to minimize effects of ion fragmentation, scatter, and increases in ion stopping power. Charge and velocity were determined to significantly affect the spectra of possible energy deposition events.

Based on the FLUKA simulations, for ions of equal stopping power (100 keV $\mu \mathrm{m}^{-1}$ ), the Ti-48 ion imparted the lowest LET value to $1 \mu \mathrm{~m}$ thick water slabs. Due to its higher velocity, the Ti-48 ion experienced the most delta-ray escape from the target slab. Ions of equal velocity ( $600 \mathrm{MeV} \mathrm{n}^{-1}$ ) were shown to deposit LET values proportional to $Z^{2}$.

Earlier studies implemented an amorphous track structure model to predict radial dose around an ion track. The methods used in this research simulated a cylindrical geometry to provide radial dose measurements, similar to the amorphous track model.

The FLUKA code simulated delta-ray penumbras of the same radii as the Chatterjee calculation. The simulated data showed a larger percentage of dose to be deposited within a 5 nm radius, compared to the Chatterjee calculation. This was primarily due to the fact that the FLUKA code doesn't transport electrons below 1 keV , so those electrons were considered to be deposited in the track core. The lower-velocity ions deposited a larger percent of dose for radial distances inside $5 \mu \mathrm{~m}$. The C-12 ion deposited the largest dose inside a $1 \mu \mathrm{~m}$ radius. The Ti-48 ion imparted the lowest dose for this dimension but produced a delta-ray penumbra that extended over a 5 mm radius. Radial dose trends were the same for ions of equal velocity. The delta-ray penumbrae extended over the same volumes with dose varying as a function of $Z^{2}$.

Delta-ray equilibrium was determined to be a significant factor in simulating radial dose measurements for radii greater than $5 \mu \mathrm{~m}$. To provide delta-ray buildup, significant target thicknesses were required to be placed in front of the target slabs in the FLUKA code geometry. Increased buildup-depth influenced radial scattering of the primary ion that complicated radial-dose measurements at distances near the track core.

To further investigate the spatial distribution of dose by the delta-ray penumbra, a voxel geometry was simulated in the FLUKA code. This method was used to calculate the dose and particle fluence for specific sites. The results described the number of voxels that received a corresponding dose from both the primary ion and by the delta-ray penumbra. The higher-velocity ions imparted their dose over most of the voxels, while the lower-velocity ions imparted their dose near the primary ion track. Out of 1 million voxels in the mesh cube geometry, the Ti-48 ion affected 1 million, while the $\mathrm{C}-12$ ion
affected only 37,607 voxels. The Be-8 ion affected even fewer, although it did not penetrate the entire target, due to its low velocity. Neglecting the $\mathrm{Be}-8$ ion, the $\mathrm{C}-12$ ion deposited the most energy across the 1 mm thick target ( $\sim 125 \mathrm{MeV}$ ), while the Ti-48 ion deposited the least ( $\sim 91 \mathrm{MeV}$ ). Physical target damage was described by the cumulative dose and particle fluence values across all voxels. The values were set relative to the Si 28 ion value to establish a relative damaging ability. The $\mathrm{Ca}-40$ ion imparted the most dose-related damage, while the Ti-48 ion imparted the most particle fluence-related damage. These two ions affected far more targets than the other ions.

The cylindrical mesh geometry simulated 1 million target voxels inside a $10 \mu \mathrm{~m}$ thick cylinder having a radius of $5 \mu \mathrm{~m}$. Radial dose was calculated, based on the FLUKA data. The radial trends were similar to the Chatterjee data, but predicted less dose. This effect was due to a lack of delta-ray equilibrium in the thin target. The quotient of voxel dose per electron fluence was established to describe the stopping power of the delta rays created by each ion. Slower ions created slower delta rays. The Be- 8 ion produced delta rays with the highest stopping power. The $\mathrm{C}-12$ ion was shown to produce the most delta rays. Those delta rays were of relatively low velocity, so the C-12 ion imparted the most dose and fluence-related damage to voxels in the cylindrical mesh geometry.

The relative damage values were averaged over the two mesh geometries. The Si-28 ion was determined to be the most damaging for dose-related damage, while the Ca-40 ion was the most damaging for particle fluence-related damage. The analysis performed in this research focused on both the high-ionization density within a cell
nucleus-sized volume, as well as the low-ionization density created the delta-ray penumbra extending over the range of many cell volumes. This outer region is more similar to the diffuse ionization density of photon irradiation, while inside the cell nucleus lies the densely-ionizing track that makes heavy ions so damaging. This research did not attempt to predict biological endpoints. The conclusions drawn here relate the total damage imparted by GCR in reference to each other. Damage was described by energy deposited and particle fluence in small sites.

This research focused on the damaging ability of ions with $100 \mathrm{keV} \mu \mathrm{m}^{-1}$ stopping powers because their corresponding LET values have the highest quality factor for calculating dose equivalent. The analysis performed in this research could be reproduced for a single ion at different stopping power values. Variations in delta-ray penumbrae have been shown to vary as a function of primary ion velocity. The primary ion charge only designates the magnitude of secondary electrons produced. Spatial distribution of dose is determined by velocity, and its magnitude is simply a function of $Z^{2}$. At equal velocity, ions with higher charge have shorter range so choosing proper target geometries presents a challenge for comparing different ions.

Further research is needed to predict the biological risks associated with heavy ions. This dissertation thoroughly describes how the effects of charge and velocity impact resulting physical interactions and secondary-particle production. Radiation biology projects can utilize this information to better predict the microdosimetry within cellular targets in heavy ion-irradiation experiments.

## Future Work

The methods utilized in this research could be extended to include additional stopping power values, higher-velocity ions, and different target-geometry scenarios. This approach would broaden the amount of data produced here. The mesh geometry simulations would be improved by providing data based on single-ion traversals, rather than the averages determined in this research. That method would provide random sampling of the actual dose and electron fluence for individual target voxels. A separate data analysis approach would be required to process the large amount of data that would be produced. Perhaps focusing on only a single atomic number ion would simplify the work. The $\mathrm{Z}^{2}$ relationship could be utilized to relate that data to additional ions.

A separate computer code, such as GEANT4, could be utilized to perform deltaray transport below 1 keV kinetic energies. There would be significant improvement to data drawn from the cylindrical mesh geometry utilized in this research. A separate library of interaction cross sections would help to identify weaknesses of each code.

Finally, the analysis drawn from this research could be implemented into planning ion beam-line experiments. Radiobiology experiments focusing on the effect of ion charge and velocity on RBE could utilize the trends established in this research.

## APPENDIX B

## DOSIMETRY DATA FOR CUBE AND CYLINDER MESH GEOMETRIES

Table B1. Dose (Gy) deposited in voxels inside the cube mesh geometry by ions of equal stopping power ( $100 \mathrm{keV} \mathrm{um}^{-1}$ ). FLUKA data is scaled as $\mathrm{GeV}-\mathrm{cm}^{-3}$ and described in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Dose (Gy) | Bin | Be-8 <br> Voxels <br> Hit |  | O-16 <br> Voxels <br> Hit | Mg-24 Voxels Hit | Si-28 <br> Voxels <br> Hit | Ca-40 <br> Voxels <br> Hit | Ti-48 Voxels Hit |

Table B2. Electron fluence (electrons / $1000 \mathrm{~nm}^{2}$ ) in voxels inside the mesh cube by ions of equal stopping power ( $100 \mathrm{keV} \mathrm{um}{ }^{-1}$ ). FLUKA data is scaled as electrons- $\mathrm{cm}^{-2}$ and described in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Electron Fluence | Bin | $\mathrm{Be}-8$ <br> Voxels <br> Hit |  |  | Mg-24 Voxels Hit | Si-28 Voxels Hit | Ca-40 <br> Voxels <br> Hit | Ti-48 <br> Voxels Hit |

Table B3. Dose (Gy) deposited in voxels inside the mesh cube by ions of equal velocity ( $600 \mathrm{MeV} \mathrm{n}^{-1}$ ). FLUKA data is scaled as $\mathrm{GeV}-\mathrm{cm}^{-3}$ and described in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Dose (Gy) | Bin | Be-8 Voxels hit | C-12 <br> Voxels hit | 0-16 <br> Voxels hit | Mg-24 Voxels hit | Si-28 <br> Voxels <br> hit | Ca-40 <br> Voxels hit | Ti-48 <br> Voxels hit |

Table B4. Electron fluence (electrons / $1000 \mathrm{~nm}^{2}$ ) in voxels inside the mesh cube geometry by ions of equal velocity ( $600 \mathrm{MeV} \mathrm{n}^{-1}$ ). FLUKA data is scaled as electrons-$\mathrm{cm}^{-2}$ and described in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Electron Fluence | Bin | Be-8 <br> Voxels <br> hit | C-12 <br> Voxels hit | 0-16 <br> Voxels <br> hit | $\mathrm{Mg}-24$ <br> Voxels hit | Si-28 <br> Voxels <br> hit | Ca-40 Voxels hit | Ti-48 Voxels hit |

Table B5. Dose (Gy) deposited in voxels inside the cylinder mesh geometry by ions of equal stopping power ( $100 \mathrm{keV} \mathrm{um}{ }^{-1}$ ). FLUKA data is scaled as $\mathrm{GeV}-\mathrm{cm}^{-3}$ and described in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Dose (Gy) | Bin | Be-8 <br> Voxels hit | C-12 <br> Voxels hit | 0-16 <br> Voxels hit | Mg-24 <br> Voxels <br> hit | Si-28 <br> Voxels hit | Ca-40 <br> Voxels hit | Ti-48 <br> Voxels hit |

Table B6. Electron fluence (electrons / $1000 \mathrm{~nm}^{2}$ ) in voxels inside the mesh cylinder by ions of equal stopping power $\left(100 \mathrm{keV} \mathrm{um}^{-1}\right)$. FLUKA data is scaled as electrons- $\mathrm{cm}^{-2}$ and described in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Electron fluence | Bin | Be-8 <br> Voxels hit | C-12 <br> Voxels hit | 0-16 <br> Voxels hit | Mg-24 <br> Voxels hit | Si-28 <br> Voxels <br> hit | Ca-40 <br> Voxels hit | Ti-48 <br> Voxels hit |

Table B7. Dose per electron fluence ( $\mathrm{Gy} /$ electrons- $1000 \mathrm{~nm}^{3}$ ) in voxels inside the cylinder mesh geometry by ions of equal stopping power ( $100 \mathrm{keV} \mathrm{um}^{-1}$ ). FLUKA data are presented as $\left(\mathrm{GeV} / \mathrm{cm}^{3}\right.$ per electron $/ \mathrm{cm}^{2}$ ) in the 'Bin' column. Un-hit voxels appear in the first row for each ion. The number of hit voxels is summed and listed at the bottom of the table.

| Dose / <br> Electron | Bin | Be-8 <br> Voxels hit | C-12 <br> Voxels hit | 0-16 <br> Voxels <br> hit | Mg-24 <br> Voxels <br> hit | Si-28 <br> Voxels hit | Ca-40 <br> Voxels hit | Ti-48 <br> Voxels hit |

## VITA

Bradley William Cox received his Bachelor of Science degree in mechanical engineering from The University of Texas at Austin in 2003. He entered the nuclear engineering program at Texas A\&M University in August 2007 to begin his graduate studies and completed his Ph.D. in nuclear engineering in 2011. In 2008, he was awarded the National Space Biomedical Research Institute's doctoral fellowship in the field of space life sciences. His research interests focus on the health effects following exposure to the space radiation environment during long-term space missions.

Brad may be reached through the Department of Nuclear Engineering, Texas
A\&M University, College Station, TX 77843. His email is cox.bradw@gmail.com.
