ABSTRACT

The DNA “Jigsaw Puzzle” Structure Model: The Case Studies of the Rice and Yeast Genomes. (December 2008)

Yun-Hua Liu, B.S., National Taiwan University

Chair of Advisory Committee: Dr. Hongbin Zhang

How does DNA make the abundant and diverged life world? To address this question, a DNA “Jigsaw Puzzle” structure model was proposed and first tested by comprehensively analyzing the genome of the model dicot plant, *Arabidopsis thaliana*. However, it is unknown whether this model is held in other species. Here we report the studies of the DNA structure model using the monocot plant model species, rice (*Oryza sativa*), and the single-celled model species, yeast (*Saccharomyces cerevisiae*). Analyses of the genomes sequenced so far revealed that the genome of an organism consists of a limited number of sequence-specialized, so-called fundamental function elements. For a higher organism, these elements often include genes (GEN), retro-transposable elements (RTE), DNA transposable elements (DTE), simple sequence repeats (SSR) and low complex repeats (LCR). Datasets were developed for RTE, DTE, SSR, LCR and GEN as well as genes categorized into different function categories from the sequences of the rice and yeast genomes using appropriate window sizes. The datasets were subjected to statistical analyses to test the DNA “Jigsaw Puzzle” structure model in terms of the unambiguousness, correlation, uniqueness and selection of their genome-constituting element arrays. The analyses were conducted with a series of window sizes of the sequences at both the whole genome and individual chromosome levels, both including and excluding the centromeric regions. The results showed that all fundamental function elements of the genomes as well as the genes categorized into different function categories were arrayed in the genomes in an unambiguous manner resembling linear “Jigsaw Puzzles” at the whole genome and/or individual chromosome levels, no matter

whether the centromeric regions were included or excluded. The analyses revealed that arraying of the genomic elements was correlated significantly and uniquely for each chromosome and each species. This further confirmed the non-random arraying characteristic of the genomic elements for the DNA “Jigsaw Puzzle” structure model and suggested that the DNA “Jigsaw Puzzle” structure is unique for an organism, which has probably resulted from natural selection. These results unambiguously support the hypothesis of the DNA “Jigsaw Puzzle” structure model. Since the content, arraying and interaction pattern of the fundamental function elements were shown to be unique for each organism, variations of an organism in its DNA “Jigsaw Puzzle” array would lead to phenotypic variations, thus resulting in different organisms. Moreover, the fundamental function elements constituting a genome, as the four nucleotides (A, T, G and C) of DNA, could be arrayed into an infinite number of DNA molecules, thus giving different forms of organisms. Therefore, the DNA “Jigsaw Puzzle” structure model would provide a novel, but convincing explanation for the abundance, diversity and complexity of living organisms in the world.

ACKNOWLEDGEMENTS

I am very grateful to my committee chair, Dr. Hongbin Zhang, who always gave me strong support and valuable suggestions on my studies. I thank him for giving me the chance to experience this interesting genomics research. I deeply appreciate his great help and advice throughout this research and thesis work. I would also like to thank my committee members, Dr. David H. Byrne and Dr. Ruzong Fan, for their guidance and help throughout the course of this research.

Acknowledgements are also given to Mr. James J. Huang for his assistance at developing computer programs and dataset establishments used in this research, and my colleagues in Dr. Hongbin Zhang's laboratory and my friends for their kind help and encouragement.

Finally, I would like to present my great appreciation to my parents, Ching-Suei Liu and Hsiu-Yuan Lai, and my elder brother, Yao-Hsien Liu, for their endless love, support and encouragement.

CHAPTER I

INTRODUCTION

There are probably trillions of organisms that differ in biology, morphology and complexity in the biosphere of the globe. The discoveries of DNA as the genetic materials of the organisms and its double helix structure in the last century have shed light to decipher the mystery of the organisms. However, it remains mysterious how the double helix DNA makes the abundant and diverged life world in terms of biology, morphology and complexity [1, 2]. Therefore, deciphering the underlying mechanisms of how DNA controls the abundance, diversity and complexity of the organisms has become an interesting subject in genetics and evolutionary biology.

Traditionally, it has been accepted widely that the abundance, diversity and complexity of the life world are attributed to the variation of genes. Nevertheless, the recent findings resulted from the large-scale genome-wide sequencing projects have cast a challenge on the traditional concepts and knowledge. It was found that the attributions of the organism complexity and diversity to variations of genes, including those in nucleotide sequence and gene number, are limited, even between diverged organisms. Consequently, the ruling role of gene variation in controlling organism's abundance, diversity and complexity is becoming doubtful. Therefore, several new hypotheses have been proposed recently to address the question about the abundance, diversity and complexity of organisms, in addition to the gene variation hypothesis. These include gene network and regulation, RNA alternative splicing, and the DNA "Jigsaw Puzzle" structure model.

The gene variation, including the numbers of genes and the variation in their nucleotide sequences, has been accepted widely to be responsible for the observed

This thesis follows the style of Genomics.

variations between diverged species. Nevertheless, the findings from recent genome-wide sequencing, annotation and comparative sequence analyses have questioned the role of gene variation in life abundance, diversity and complexity. It has been found that the numbers of genes are relatively consistent between diverged species while they are extremely different in genome size, biology, morphology and complexity. For instance, human has a genome size of about 3,300 Mb/1C, whereas the dicot plant model species, *Arabidopsis thaliana*, has a genome size of about 120 Mb/1C [3]. The genome size of the former is nearly 30-fold larger than that of the latter. In biology, morphology and complexity, there is no doubt that these two species are extremely different. However, both of them have approximately 26,000 genes. It is apparent that the variation of the number of genes could not well account for the abundance, diversity and complexity of organisms. At the gene nucleotide sequence level, it has also been found that diverged species share a similar set of genes. A pair of good examples in this regard is between human and chimpanzee. Although human and chimpanzee are dramatically diverged in biology, morphology and complexity, comparative analyses showed that their genes have a nearly 99% identity at the nucleotide sequence level [4]. The genome sequencing and annotation results have indicated that the gene variation itself, though it contributes to, at a significant level, does not provide a reasonable explanation for the abundance, diversity and complexity of organisms in the world.

Second, the abundance, diversity and complexity between diverged species were hypothesized to be attributed to gene network and regulation. In other words, organisms differing in biology, morphology and complexity have different gene networks and regulation patterns. Nevertheless, the results of several studies did not support this hypothesis. Snel and his colleagues [5] studied the diversity of gene network and co-regulation between the lineages of eukaryotes and prokaryotes, and within each of the lineages. It was found that the gene co-regulation and network were highly conserved, not only within eukaryotic or prokaryotic organisms, but also between eukaryotic and prokaryotic organisms even though they were extremely

different in biology, complexity, morphology, and genome size. In the lineage of eukaryotes, over 76% of the gene co-regulation cases studied were found to be conserved between *Caenorhabditis elegans* and yeast (*Saccharomyces cerevisiae*) while they were estimated to be diverged 1.5 billion years ago. In the lineage of prokaryotes, 80% of the gene co-regulations examined was found to be conserved between *Escherichia coli* and *Bacillus subtilis*. These findings suggest that gene networks and co-regulations are conserved between diverged species, even though obvious variations exist among these species. However, such a degree of variation could not sufficiently account for the observed abundance and diversity of organisms in biology, complexity and morphology. The highly conserved gene co-regulations between diverged species may be of indication of house-keeping or ancestral functional genes rather than the diversity and complexity of organisms in genetics and evolution.

Third, RNA alternative splicing was proposed to make the abundant living forms that were different in biology, morphology and complexity in the world. RNA alternative splicing is a mechanism in which a single gene gives multiple transcripts based on which combination of exons incorporated into multiple matured mRNA transcripts, thus being translated into multiple proteins and further affecting phenotypes and complexity of organisms. It was found that a human gene, on average, contains between 10 and 15 exons and encodes three or more different proteins as a result of RNA alternative splicing [3]. Related species were proposed to have similar abilities of RNA alternative splicing that would yield similar gene products; whereas diverged species would have different alternative splicing abilities. Brett *et al.* [6] studied RNA alternative splicing by using the expressed sequence tags (ESTs) of genes and mRNAs derived from seven diverged species: human, mouse, rat, cow, fruit fly, worm, and *A. thaliana*. The result showed that there were no large differences observed in the proportion of genes that pursue RNA alternative splicing between the highly diverged species, classifying into mammals, insects, worms and plants, the variations being only 3 - 13%. Therefore, RNA alternative splicing may affect the gene products of the

same coding regions, but it may not significantly contribute to the abundance, diversity and complexity of the living organisms.

The hypotheses described above, including gene variation, gene network and co-regulation, RNA alternative splicing or their combinations, in spite of contributing to some degree, does not provide a convincing explanation of the abundance, diversity and complexity of living organisms observed in the world. Hence, Wu *et al.* [7] proposed the DNA “Jigsaw Puzzle” structure model. It was hypothesized that DNA is structured from a limited number of sequence-specialized fundamental function elements, including genes, DNA transposons, retrotransposons, simple repeats and low complex repeats, in a form resembling a linear “Jigsaw Puzzle”. The content, array and interaction of the fundamental function elements are responsible for the observed abundance, diversity and complexity of organisms. This is very similar to the manner in which how four nucleotides (A, T, G and C) make DNA molecules. Different arrays of the four nucleotides in DNA strands would result in different DNA molecules, thus giving different organisms.

In particular, the DNA “Jigsaw Puzzle” structure model [7] is specified by the following: (1) The elements or components constituting a DNA molecule must be arrayed in an unambiguous manner, as a linear “Jigsaw Puzzle”. Therefore, the array pattern is unique for a particular DNA molecule. (2) Distribution correlation exists between different elements constituting a DNA molecule and it is unique for a particular DNA molecule. (3) The array and distribution correlation of the elements are affected by chromosome rearrangement such as genetic recombination, nucleotide sequence translocation, inversion and insertions/deletions, and modified by nucleotide variations such as nucleotide substitutions. (4) Changing the content and/or order of the array would alter the activity level and/or mode of genes in the array, thus affecting phenotype. Therefore, phenotypic variations are largely attributed to the genomic element array and/or interactions. (5) The element array and distribution correlation of a DNA molecule are subjected to natural selection. The array that biologically provides advantageous fitness to the organism is selected and maintained in the population

whereas those having disadvantages to fitness such as deleterious ones are rapidly eliminated from the population by natural selection. Because the first and second points above are the most essential basis of the DNA “Jigsaw Puzzle” structure model, we had our focus on characteristics of the DNA structure model in this study.

The DNA “Jigsaw Puzzle” structure model was first tested by using the genome sequence of *A. thaliana*, which is the model species for molecular biology and genomics studies of dicot plants [7, 8]. It was found that the arraying, organization and interaction of the fundamental function elements constituting the *A. thaliana* genome support unambiguously for the hypothesis of DNA “Jigsaw Puzzle” model. Moreover, it was also shown that the arrays and interactions of the fundamental function elements were subjected to natural selection. However, it remains unknown whether the proposed model is held in other species.

In this study, we tested the DNA “Jigsaw Puzzle” structure model using the monocot plant model species, rice (*Oryza sativa*) and the single-celled, eukaryotic model species, yeast (*Saccharomyces cerevisiae*). Testing the arraying, organization and interactions of the fundamental function elements constituting the rice and yeast genomes would provide an additional line of evidence for the DNA “Jigsaw Puzzle” structure model.

Rice is one of the most important food crops in the world. Importantly, it is the model species of monocot plants in genomics and molecular biology research, and it represents an evolutionary lineage of the plant kingdom differing from *A. thaliana* previously studied by Wu and his colleagues [7]. Rice has a genome size of about 400 Mb/1C, distributed in 12 chromosomes. This number is more than three-fold larger than that of *A. thaliana*. It is the first crop plant whose genome has been completely sequenced [9] and annotated.

About 35% of the rice genome was found to be composed of transposable elements [10] and a total of 37,544 non-transposable elements were annotated while masking the pseudomolecules of the genome for repetitive sequences using the *ab*

ab initio gene finder FGENESH. The Institute for Genomic Research (TIGR) provides a rice genome sequence annotation of gene content in their database for community with a resource of the rice genome [11-12]. The rice genome sequences were processed with multiple *ab initio* gene finders, including FGENESH (<http://www.softberry.com>), Genemark.hmm (rice matrix; <http://opal.biology.gatech.edu/GeneMark/eukhmm.cgi>), Genscan (Arabidopsis matrix; <http://genes.mit.edu/GENSCAN.html>), Genscan (maize matrix; <http://genes.mit.edu/GENSCAN.html>), and GlimmerM (rice matrix; http://www.tigr.org/tdb/glimmerm/glmr_form.html). The output from the gene prediction programs and database searches were stored in *osa1*. Working models were generated using the FGENESH output, and putative identification for the genes was obtained from the most significant database match while models with no significant database match were labeled as hypothetical proteins. The database of TIGR is available through web-based interfaces, FTP downloads, and a Distributed Annotation System. Besides, more integrating genomic information about the rice genome is available at public web-based databases or on-line resources from different research groups.

Saccharomyces cerevisiae is an ideal eukaryotic microorganism for biological studies because of its small genome size (about 12 Mb/C), distributed in 16 chromosomes, and easy genetic manipulation [13]. Furthermore, because its genome is well-sequenced, well-annotated and well-characterized in functionality, it is suited for our research purposes. A database named the Yeast Genome Database of Munich Information Center for Protein Sequence (MIPS) was established for annotating the yeast genome. It is a primary source of the related or derived information and builds the repository for the European functional analysis projects. Moreover, the Saccharomyces Genome Database (SGD), which was set up for providing more powerful tools for comparison and integrating genomic information at a genome-wide scale, collects and organizes biological information about the genes and proteins of yeast from the scientific literature, and presents this information on individual Locus Pages for each

yeast gene through web-based databases [14]. The online resources and databases of yeast and rice provided platforms, resources and tools for this study.

In this study we analyzed the genome sequences of rice and yeast comprehensively to further test the DNA “Jigsaw Puzzle” structure model. The arraying, organization and interactions of the fundamental function components constituting the genomes were investigated. Furthermore, a sample of genes categorized into different function categories was selected to test their distribution and interaction patterns. This study provides not only a new line of evidence for the DNA “Jigsaw Puzzle” structure model, but also new knowledge about the rice and yeast genomes and new information for deeper understanding of the genomes.

CHAPTER II

MATERIALS AND METHODS

2.1 Data Extraction

Before exploring how the fundamental function elements, i.e., genes (GEN), retro-transposable elements (RTE), DNA transposable elements (DTE), simple sequence repeats (SSR) and/or low complex repeats (LCR), are structured into the rice or yeast genome, each of the elements was extracted along the DNA pseudomolecule of each chromosome of the genomes in an appropriate window size (see below). Moreover, we also collected the gene distribution data of a sample of function categories along each chromosome of the genomes using the window size.

2.1.1 Rice Data Extraction

We first downloaded the nucleotide sequences of the whole rice genome from the database of the International Rice Genome Sequencing Project (<http://rgp.dna.affrc.go.jp/IRGSP/>) released as Build 4.0 Pseudomolecules. Then, we segmented the genome sequences with a window size of 500 kb along each chromosome of the genome, as described by Wu *et al.* [7]. As a result, 46 – 88 segments were generated from each of the 12 rice chromosomes (Table 1). The segments of the sequences were scanned by the program RepeatMasker [15] to extract for the counts of RTE, DTE, SSR and LCR, respectively, in each window. RepeatMasker is a program that screens DNA sequences for interspersed repeats and low complexity sequences, and compares the query sequence against one or more files of sequences from target species in the RepeatMasker libraries. The sequences in the libraries provided within the RepeatMasker are consensus sequences derived from alignment of multiple copies of interspersed, satellite or low complex repeats. The count numbers of RTE, DTE, SSR and LCR in each 500 kb window along a chromosome were collected by this program.

The sequence comparisons in the program RepeatMasker were performed by WU-Blast (W. Gish, <http://blast.wustl.edu/>).

Although different types of repeat elements could be collected by the RepeatMasker, the numbers of genes and genes categorized into different functions in each window could not be done with it. So, we extracted the numbers of genes within each 500-kb segmented window from the rice genome annotation group of TIGR (<http://www.tigr.org/tdb/e2k1/osa1/>) with released Version 5.0. For the genes categorized into different functions along the rice genome, we used the Gene Ontology (GO) to classify gene function categories. The GO Consortium (<http://www.geneontology.org/>) was established to produce a structured, precisely defined, common and controlled vocabulary for describing the roles of genes and gene products in any organisms [16-21]. For this study, we randomly selected the genes categorized into 34 function categories from a total of 106 GO terms of rice from three main GO categories: molecular function, cellular component, and biological process (Table 2). The genes belonging to each of the selected function categories were extracted against their GO accession numbers in the TIGR's database in each 500-kb window along each chromosome of the genome. The genes with the same GO terms were categorized into the same function category.

2.1.2 Yeast Data Extraction

A similar procedure to that used in rice was employed to extract the datasets of the yeast genome. We downloaded the nucleotide sequences of the yeast genome from the *Saccharomyces* Genome Database (SGD) (<http://www.yeastgenome.org/>). The genome sequence was segmented using a 10-kb window size and subjected to analysis with the RepeatMakser to extract RTE, DTE, SSR and LCR in the yeast genome. The number of each element in 10 kb-window sizes was extracted by RepeatMasker against *S. cerevisiae*.

The numbers of genes were extracted in each 10-kb window along individual chromosomes from the SGD database. As used in the rice data extraction above, GO terms were employed to categorize the yeast genes by their products from the SGD database. Twenty gene categories that each had 33 or more gene counts in the entire yeast genome were selected for this study because small numbers of gene counts are not suited for distribution analysis by using statistical tools (Table 3). Genes with the same GO terms were categorized into the same function category.

To have a further insight into the rice and yeast genomes, we examined the density variations of each fundamental function element and gene function category among the 12 rice chromosomes and 16 yeast chromosomes by ANOVA. Fisher's LSD was used to test the mean density differences of each element or gene function category between different chromosomes.

2.2 Distribution independence test of genomic fundamental function elements and genes categorized into a function category in the rice and yeast genomes

The window size of sequence and centromeric regions were considered to be major factors that may influence the results of the genomic element distribution analysis [7]. Therefore, we first tested a series of window sizes to be used for statistical analyses. As defined by Wu *et al.* [7], an appropriate window size should provide (1) sufficient large values of variables that could properly reflect the distribution variation of each element along a chromosome, and (2) a sufficient number of variables that are suited for statistical analysis. Although the latter is not problematic for rice because its chromosome pseudomolecules have a size of 23 to 44 Mb, it may be of consideration for yeast because its chromosome pseudomolecules have only a size of 240 – 1,600 kb. To determine the appropriate window size for the rice dataset analysis of both fundamental function elements and genes with different functions using statistical tools, we tested the window sizes of 500 kb and 1000 kb [7]. To determine the appropriate window size for

the yeast dataset analysis of both fundamental function elements and genes with different functions using statistical tools, we tested the window sizes of 10 kb, 20 kb, 30 kb, 40 kb, 50 kb, 60 kb, 70 kb, 80 kb and 100 kb [7].

Previous studies showed that rice centromeres were abundant in repetitive sequences [22]. To estimate the potential influences of centromere-specific repeat elements on our analyses, we excluded the centromeric regions of all chromosomes, and then we tested the distributions of fundamental function elements against the random distribution model by the Chi-square Goodness-of-Fit test, as described by Wu *et al.* [7]. At both individual chromosome and whole genome levels, the results excluding centromeric regions were very similar to those including the centromeric regions, suggesting that the regional abundant repeat elements had no significant influences on our analyses of this study. This result was totally in agreement with those of Wu *et al.* [7] obtained in a similar analysis of the *A. thaliana* genome. Therefore, we analyzed the datasets of rice and yeast only at the whole genome and chromosome levels in this study.

To test whether each of the genomic fundamental function elements and the function categories of genes is distributed randomly or non-randomly along the whole genome and individual chromosomes, Chi-Square Goodness-of-Fit Test was conducted against the null hypothesis that each element is randomly distributed in the genome. The mean value of each element in the whole genome or individual chromosomes with the above window sizes was used as the expected value, and the actual number of each element in each window used as the observed value with the degree of freedom $n - 1$, where n represents the number of the sequence windows along the chromosome or the whole genome. Three levels of the two-tailed significance were established at $\alpha \leq 0.05$ (indicated by red color), 0.01 (indicated by green color) and 0.001(indicated by blue color).

2.3 Distribution correlation test of the genomic fundamental function elements and genes categorized into different function categories in the rice and yeast genomes

For such analyses, the phenomenon that a single gene has two or more functions is of significant consideration, in addition to the above window size and centromeric factors. Therefore, we first re-compiled the datasets of both the rice and yeast genomes pair-wisely by excluding the genes with both functions to prevent from being counted in both function categories of the pair under comparison. The Spearman's rank correlation coefficient (r_s) was then used to test the distribution correlation between the fundamental function elements and the genes categorized into different function categories. The results of such studies could provide not only an additional line of evidence for the DNA "Jigsaw Puzzle" structure model, but also useful information on the fundamental function element relationships and networks. The Spearman's rank correlation coefficient (r_s) between each pair of the elements or gene function categories was calculated by using the program SPSS 14.0 at the individual chromosome and whole genome levels. Three levels of the two-tailed significance were established at $\alpha \leq 0.05$ (indicated by red color), 0.01 (indicated by green color) and 0.001(indicated by blue color). Before calculating the Spearman's rank correlation coefficient, Q-Q plots were applied to test the distribution normality of each element.

The Spearman's rank correlation coefficient was also used to test the distribution correlation between each fundamental function element and genes categorized into each function category. The correlations were determined by the program SPSS 14.0 at the whole genome level for both rice and yeast. The two-tailed significance was established at three levels: $\alpha \leq 0.05$ (indicated by red color), 0.01 (indicated by green color) and 0.001 (indicated by blue color).

CHAPTER III

RESULTS

3.1 The constitution of the rice and yeast genomes

To determine the constitution of DNA contained in each chromosome of the rice and yeast genomes, we first looked for all related databases and literatures about the rice and yeast genomes. No genome-wide, comprehensively statistical dataset of any of the fundamental function elements was found for the rice or yeast genome. Hence, we explored the fundamental function elements and genes categorized into different functions via web-based public databases, annotation with the program RepeatMasker and GO classification.

3.1.1 The constitution of the rice genome

The genome sequence pseudomolecules of rice (*O. sativa* spp. *japonica*) consisted of a total of 372,077,801 base pairs [9]. We segmented the pseudomolecules sequences in 500-kb size into a total of 749 windows, with the numbers of segmented windows along each chromosome ranging from 46 to 88 (Table 1). The FASTA file of the segmented sequence in each window was analyzed with the program RepeatMasker against *O. sativa*. A total of 71,287 RTEs, 169,691 DTEs, 43,009 SSRs, and 48,632 LCRs were found. Further, the TIGR database showed there were a total of 41,836 genes (GENs) contained in the genome after the genes belonging to transposable elements were excluded. This result suggests that the rice genome is made of approximately 41,836 GENs, 71,287 RTEs, 169,691 DTEs, 43,009 SSRs, and 48,632 LCRs, being arrayed into 12 DNA molecules contained in the 12 chromosomes of the rice genome.

3.1.2 The constitution of the yeast genome

For the yeast genome analysis, we downloaded a total of 12,079,954 base pairs nucleotide sequence from the SGD. Analysis of the sequence using the program RepeatMasker found 524 RTEs, 1,187 SSRs and 1,288 LCRs, respectively (Table 4). Nevertheless, no DTE was identified in the sequence. The SGD showed that there were a total of 6,576 genes (GENs) contained in the genome after the genes categorized into transposable elements were excluded. This suggests that the yeast genome is made of 6,576 GENs, 524 RTEs, 1,187 SSRs and 1,288 LCRs, being arrayed into 16 DNA molecules contained in the 16 chromosomes of the yeast genome.

We compared the constitutions of the rice and yeast genomes with that of *A. thaliana* for which genome-wide statistical datasets were available for each element constituting the genome [7]. A significant difference among them was found to be the RTE/DTE ratio. Rice, yeast and *A. thaliana* represent monocot plants, single-celled eukaryotic organisms and dicot plants, respectively. The monocot rice has 2.38-fold more DTEs than RTEs whereas the dicot *A. thaliana* has 1.38-fold more DTEs than RTEs. For the single-celled yeast, there is no DTE in its genome while it contains 524 RTEs. Although further investigations are needed in the genomes of additional species, the difference in the genome constitution of the three species may represent a feature of monocot plants, dicot plants and lower-level eukaryotic organisms, respectively.

To further characterize the genomes of rice and yeast, we calculated the mean counts of each fundamental function element and the genes of each function category at the individual chromosome and whole genome levels in 500-kb windows for rice, and 60-kb windows for yeast. The differences in density of each element or gene function category between chromosomes were tested with ANOVA, followed by Fisher's LSD. For the rice genome, the densities of DTE and RTE of each chromosome were apparently larger than those of GEN, SSR and LCR, suggesting that the rice genome is more abundant in RTE and DTE than GEN, SSR and LCR (Table 1). In comparison between the 12 rice chromosomes, the densities of RTE in chromosomes 1, 2 and 3 were significantly lower than those of chromosomes 4 through 12 whereas the densities of

GEN in the three chromosomes were significantly higher than those of chromosomes 4 through 12 (Table 5). The density of DTE was the lowest in chromosome 4, being significantly lower than those of the rest of chromosomes. The SSR-most dense chromosomes were funded to be chromosomes 2 and 3, whose SSR densities were significantly higher than those of chromosomes 4, 7, and 10 through 12. The density of LCR was the lowest in chromosome 4, which was significantly lower than those of chromosomes 1 through 6. For the genes categorized into different function categories, their densities varied significantly between chromosomes, even though no consistent pattern could be identified (Table 6).

For the yeast genome, significant differences were detected only in a limited number of chromosome pairs of its 16 chromosomes in densities of RTE and SSR, but not in the densities of LCR and GEN (Table 7). This suggests that although the densities of RTE and SSR are different between the yeast chromosomes, but those of GEN and LCR are alike among the chromosomes. For the genes categorized into different function categories, the similar results were obtained. No significant differences were detected between the yeast chromosomes in most of gene function categories while significant differences were detected between some chromosomes in some of the gene function categories (Table 7). In comparison with the rice genome, yeast chromosomes have a more uniform density of the fundamental function elements and genes with different functions.

3.2 Distribution independence test of fundamental function elements and genes categorized into a function category

3.2.1 Arraying of each genomic element in the rice genome

One of the predominant characteristics of the DNA “Jigsaw Puzzle” structure model [7] is that the fundamental function elements constituting a genome must be arrayed non-randomly, resembling a linear “Jigsaw Puzzle”. As shown above, the rice

genome consists of 12 chromosomal arrays of 41,836 GENs, 71,287 RTEs, 169,691 DTEs, 43,009 SSRs, and 48,632 LCRs. To test whether these elements are arrayed randomly or non-randomly in the genome and each chromosome, we tested their distribution along the whole genome and individual chromosomes by Chi-square Goodness-of-Fit Test. The null hypothesis was that each of the elements was distributed randomly. Since consistent results were obtained from the datasets of both windows (500- and 1000-kb) analyzed, the results only from the analysis of 500-kb windows are presented here.

The chi-square values of all five fundamental function elements, GEN, RTE, DTE, SSR and LCR, were significant at $\alpha \leq 0.001$ (Table 8) at the levels of both the whole genome and individual chromosomes from chromosome 1 through 12. The result rejected the null hypothesis, indicating that the fundamental function elements constituting the rice genome are arrayed non-randomly in the rice chromosomes and whole genome. This result strongly supports the DNA “Jigsaw Puzzle” structure model proposed by Wu *et al.* [7] in the dicot plant, *A. thaliana*, in which the DNA was shown to be structured from its fundamental function elements resembling a linear “Jigsaw Puzzle”.

Furthermore, we analyzed the distribution of the genes categorized into 34 function categories that were selected randomly to further verify the non-random distribution pattern of the rice genes in its chromosomes and whole genome using the same method as described above. The chi-square values of all gene function categories analyzed significantly ($\alpha \leq 0.001$) deviated from the null hypothesis at the whole genome level, except for the genes categorized into “Embryonic development” and “Chromatin binding” (Table 8). This result indicates that the genes categorized into a function category were also arrayed non-randomly in the rice genome. At the individual chromosome levels, although the distributions of the genes categorized into some function categories were not significantly deviated from the random distribution null hypothesis, the genes categorized into a vast majority of the 34 function categories were distributed non-randomly at a significance level of $\alpha \leq 0.001$ (Table

8). This indicates that the genes categorized into individual function categories are also arrayed non-randomly in the rice genome, further supporting the DNA “Jigsaw Puzzle” structure model.

3.2.2 Arraying of the genomic elements in the yeast genome

Similarly, we analyzed the distribution of each of the genomic fundamental function elements and genes categorized into 20 function categories using the Chi-square Goodness-of-Fit Test. For this experiment, we analyzed the sequence using 9 window sizes, including 10-, 20-, 30-, 40-, 50-, 60-, 70-, 80-, and 100-kb windows. It was found that the results were consistent from 60-kb through 100-kb windows (not shown); therefore, the window size of 60 kb was selected for the statistical analysis. At the whole-genome level, the distribution of all four fundamental function elements (DTE is absent in the yeast genome), GEN, RTE, SSR and LCR, were significantly ($\alpha \leq 0.001$) deviated from the random distribution null hypothesis. This supports the DNA “Jigsaw Puzzle” structure model. Nevertheless, at the individual chromosome levels, the distributions of these four fundamental function elements significantly deviated from the null hypothesis for some of the 16 yeast chromosomes, but not for others (Table 9). Of the four elements, the distributions of RTE and GEN were much more significantly deviated from the null hypothesis than those of SSR and LCR. Therefore, although the statistical significance level of the element distribution analysis at the individual chromosome level may be affected by the degrees of freedom or variables and the window sizes due to the small chromosome sizes of the yeast genome, the result supports the DNA “Jigsaw Puzzle” structure model.

For the genes categorized into different function categories, the distributions of the genes categorized into “DNA binding”, “Nucleus”, “Cytoplasm”, “Translation”, “Endocytosis” and “Response to drug” were arrayed non-randomly at a significance level of ≤ 0.05 at the whole genome level; however, those of others were not. Similar results were obtained at the individual chromosome levels, in which the distributions of

only some of the gene categories analyzed were arrayed non-randomly at a significance level of ≤ 0.05 .

3.3 Correlations of distribution between the genomic fundamental function elements and genes categorized into different function categories in the rice and yeast genomes

According to the DNA “Jigsaw Puzzle” structure model proposed by Wu *et al.* [7] in *A. thaliana*, distribution correlations exist between the fundamental function elements and gene function categories at the individual chromosome and whole genome levels, and the element distribution correlation pattern of each chromosome is unique, as they are arrayed non-randomly in the genome. The unique element distribution correlation pattern of each chromosome not only reflects the consequence of natural selection, but also may provide, at least in part, a basis of gene regulation and network. Therefore, to determine whether and what relationships exist in distribution between the genomic fundamental function elements, and genes categorized into different function categories, all possible pair-wise Spearman’s correlation coefficients and their significance levels were calculated for each pair of the elements at both the whole genome and individual chromosome levels of rice and yeast.

3.3.1 Correlations of distribution between fundamental function elements

3.3.1.1 The rice genome

Table 10 shows the distribution correlation coefficients and their significance levels of the five genomic fundamental function elements at both the whole genome and individual chromosome levels. The distributions of the elements were all shown to be correlated significantly, with $|r_s| = 0.215 \sim 0.879$, at both the whole genome and

individual chromosome levels, with exceptions for five pairs of the comparisons of two chromosomes (chromosomes 2 and 3). The distributions of LCR were positively correlated with those of DTE, SSR and GEN, respectively, but negatively with that of RTE. Interestingly, RTE was correlated negatively with DTE, and GEN was positively correlated with DTE, SSR and LCR in distribution. This result is just the opposite of those observed in the dicot *A. thaliana* genome [7]. It was also interesting that the GC content was positively correlated with the distribution of RTE and negatively correlated with the distribution of SSR and LCR, but no correlation was detected in the distribution between the GC content and GEN. This is also reverse of the results of the dicot *A. thaliana* genome [7]. Although further investigation is needed, these differences may suggest the uniqueness of the DNA “Jigsaw Puzzle” structures between the monocot and dicot plants.

3.3.1.2 The yeast genome

Table 11 shows the distribution correlation coefficients and their significance levels of the four yeast genomic fundamental function elements at the whole genome and individual chromosome levels. Significant distribution correlations were detected between LCR and SSR, GEN and RTE, GEN and SSR, and GEN and LCR, but not between RTE and LCR, and RTE and SSR. The correlation directions (positive or negative) of GEN with RTE, SSR and LCR were the same as those of rice, but the correlation direction of GEN with LCR was the opposite of that in *A. thaliana* [7]. In comparison with the GC content, the RTE and SSR both were correlated with the GC content significantly; however, the yeast correlation direction was the same as that of *A. thaliana* [7], but the opposite of that of rice. These suggest that the yeast genome is also unique in its DNA “Jigsaw Puzzle” structure.

At the individual chromosome level, a limited number of the pairs between GEN, RTE, SSR and LCR were detected to be correlated significantly in distribution; however, the significant correlations were strong, as indicated by the high value of $|r_s|$,

with a range from 0.509 to 0.975. This result supports the existence of correlation in distribution among fundamental function elements and the uniqueness of the array pattern for each chromosome described in the DNA “Jigsaw Puzzle” structure model [7] even though the power of the statistical tools was found to be limited in such small sample numbers (n) and values of variables for each chromosome.

3.3.2 Correlations of distribution between genes with different functions

To further explore the uniqueness of the gene distribution along whole genome and individual chromosomes, we calculated the Spearman’s correlation coefficients and their significance levels pair-wisely between the genes categorized into 34 function categories for rice and 20 function categories for yeast. The information obtained from this experiment will also be useful for understanding the interactions and networks among the genes categorized into different function categories. For rice, the analysis was performed at both whole genome and individual chromosome levels, whereas for yeast it was conducted only at the whole genome level due to the insufficiency of the numbers of variables for statistical analysis for individual chromosomes.

3.3.2.1 The rice genome

Table 12 shows the distribution correlations and significance levels between the 34 gene function categories randomly selected from the datasets of the rice genes at the whole genome level. The arrays of most of the selected function category pairs were correlated with each other at a significance level of $\alpha \leq 0.001$, with the value of $|r_s|$ being up to 0.500. At the individual chromosome level, correlations were also detected in distribution among a number of the function category pairs compared. Although some of the function category pairs were correlated significantly between two or more chromosomes, no consistent correlation pattern was observed through all 12 chromosomes of the rice genome (Tables 13 – 24). These results support the

statement of the DNA “Jigsaw Puzzle” structure model that correlations exist among the elements constituting a genome and are unique for a DNA molecule.

3.3.2.2 The yeast genome

Table 25 shows the distribution correlations and significance levels between genes categorized different function categories at the whole-genome level. Although the statistical analysis may be affected by the limited number of genes in each function category, i.e., the values of variables, distribution correlations were detected between some of the function category pairs. Nevertheless, no distribution correlation was detected between most of the function category pairs by using the statistical tool.

3.3.3 Correlations of distribution between fundamental functional elements and genes with different functions

To dissect the distribution correlation of GEN with RTE, DTE, SSR and LCR in the genomes, we further analyzed the correlations between the fundamental function elements and genes categorized into each function category by calculating their Spearman’s correlation coefficients and significance levels pair-wisely. The analysis was performed for the rice genome at both whole-genome and individual chromosomes and for the yeast genome at the whole genome level due to its limited number of variables.

3.3.3.1 The rice genome

Table 26 shows the distribution correlations of the fundamental function elements with the genes categorized into each of 34 function categories at the whole genome level. The distributions of RTE were negatively correlated with the distributions of the genes belonging to all 34 function categories analyzed. In contrast, the distributions of DTE, SSR, LCR and GEN all had significantly positive

correlations with the arrays of genes belonging to the 34 function categories. Nevertheless, the degree of the significant correlation ($|r_s|$) varied by over 8 fold, ranging from 0.074 to 0.639. This suggests that the distributions of some of the gene function categories be more correlated with the arrays of RTE, DTE, SSR and LCR than those of others. There was no correlation detected between the GC content and the distributions of genes with different functions.

At the individual chromosome level, the numbers of significantly correlated fundamental function element/gene function category pairs were many fewer those at the whole genome level, but the degrees of the correlations were greatly increased, with a significant $|r_s|$ value ranging from 0.210 to 0.810 (Table 27). The distribution correlations of some of the fundamental function element/gene function category pairs were significant for all 12 chromosomes of the rice genome while those of others were significant only for some of the 12 chromosomes. For instance, the arrays of RTE were correlated significantly to the distributions of the genes involved in “Cellular component organization and biogenesis”, “Transcription”, “Transcription factor activity”, “Catalytic activity” and “Nucleus”, and the distribution correlations of SSR were correlated significantly with the distributions of genes categorized into “Response to stress” and “DNA binding” for all 12 rice chromosomes. Although the common distribution correlations existed across all chromosomes, the chromosome-specific correlations represented the majority of the correlations between the fundamental function elements and genes categorized into each function category. This result further supports the non-random arraying feature of the elements in the chromosomes and the uniqueness of the arrays for each chromosome. This observation may represent a consequence of natural selection.

3.3.3.2 The yeast genome

Table 28 shows the distribution correlations between fundamental function elements and genes with different functions detected in the yeast genome at the whole

genome level. Significant correlations were found between some pairs of SSR, LCR or GEN and genes with some functions, but not between RTE and the genes of the function categories. In the genome, the distributions of genes as a whole were significantly correlated with the distributions of genes categorized into “RNA binding”, “Translation”, “Protein amino acid phosphorylation”, “Ribosome biogenesis and assembly”, “Cytoplasm”, “Nucleus” and “Positive regulation of transcription from RNA polymerase II promoter”. This result suggests that arraying of the genes in the yeast genome be affected significantly by the genes categorized into the function categories. Furthermore, significant correlations were also observed between the arrays of SSR and the genes categorized into “Nucleus” and between LCR and the genes categorized into “Cytoplasm”. In other words, the genes categorized into “Nucleus” and “Cytoplasm” tends to reside at the regions where the SSR or LCR is more abundant in the yeast genome.

CHAPTER IV

DISCUSSION AND CONCLUSION

How does DNA as the genetic materials make the abundant and diverged life world? Wu *et al.* [7], for the first time, proposed the DNA “Jigsaw Puzzle” structure model to address this question and tested the model by comprehensively analyzing the genome of the dicot model plant species, *A. thaliana*. They proposed that the unique content, array and interaction of the fundamental function elements constituting a genome are responsible for the observed abundance, diversity and complexity of living organisms. As arraying of the four nucleotides in DNA strands, the fundamental function elements of DNA could be arrayed into an infinite number of DNA molecule “Jigsaw Puzzles” and thus genomes being responsible for an infinite number of organisms. This study has provided new, strong lines of evidence supporting the DNA “Jigsaw Puzzle” structure model using rice and yeast as experimental species, together with those of *A. thaliana*, making the model more universal in interpreting the abundance, diversity, and complexity of organisms in the world.

Rice is a monocot plant representing an evolutionary lineage of plants differing from that of the dicot *A. thaliana*. As discovered in the *A. thaliana* genome [7], the rice genome and chromosomes that each contains a single DNA molecule are made of non-random arrays of GEN, RTE, DTE, SSR and LCR, resembling a linear ‘Jigsaw Puzzle’. This finding is supported strongly by the following results. First, each of the fundamental function elements constituting the rice genome was found to be distributed in a non-random manner at both whole-genome and individual chromosome levels. Further dissection of the GEN element into different categories according to genes’ functions showed that genes with similar functions or categorized into the same function category was also arrayed in a non-random manner in the genome and individual chromosomes. Second, the elements constituting the rice

genome were significantly correlated in distribution in all cases tested, including those between different fundamental function elements, between genes with different functions, and between fundamental function elements and genes with different functions. The significant distribution correlations among the elements or genes further support the non-random arraying characteristic of the elements in the rice genome and chromosomes, and indicate that arraying of the elements has been subjected to natural selection. This may be of an indication, at least in part, of the elements or gene interactions and networks. Third, the distribution correlation patterns of the elements or genes for each chromosome were observed to be different from each other, suggesting that the element array of each chromosome is unique.

Yeast represents a single-celled organism. In comparison, it is much simpler in biology, morphology and complexity, and much smaller in genome size than the multiple-celled, higher-level species, rice and *A. thaliana*. Although the power of statistical tools used in this study did not seem sufficient for yeast analysis because of the small genome size (12 Mb/1C) and small chromosomes (240 – 1,600 kb) which could not give both sufficiently large sample sizes and sufficient number of variables for statistical analysis, the results similar to those of rice and *A. thaliana* were obtained for the yeast genome. All four fundamental function elements that constitute the yeast genome, GEN, RTE, SSR and LCR, were distributed in a manner that significantly deviated from the random distribution model at the whole genome level, though their distributions were not statistically significantly deviated from the random distribution model for some chromosomes. Significant distribution correlations were also observed between some of the elements or gene categories analyzed, in spite of being not between all.

The uniqueness of each DNA “Jigsaw Puzzle” has been further proven in this study. Although further investigation is needed to compare the DNA “Jigsaw Puzzles” contained in different chromosomes and organisms, element by element, the observed differences of the distribution correlation patterns of the elements or genes among different chromosomes of *A. thaliana* [7], rice and yeast (this study) and

among the three species support the uniqueness of DNA “Jigsaw Puzzle” structures for different chromosomes and different organisms. It was observed that *A. thaliana* [7], rice and yeast are different in genome constitution, with both the *A. thaliana* and rice genomes being more abundant in DTE than RTE, whereas the yeast genome having no DTE. However, the ratio of DTE/RTE of rice is 2.38, whereas that of *A. thaliana* is 1.38, the monocot rice being much more abundant in DTE than the dicot *A. thaliana*. These findings provide additional information about the uniqueness of the DNA “Jigsaw Puzzles” contained in each species. The uniqueness of each DNA “Jigsaw Puzzle” may be an indication of the consequences of natural selection for favor arrays of the fundamental function elements.

Further comparative analysis showed that conserved significant distribution correlations of the elements and gene function categories, including correlation direction, exist between rice and yeast, yeast and *A. thaliana* [7], and rice and *A. thaliana*, and among the three species. The examples of the conserved distribution correlations include those of RTE to GEN, and SSR to LCR among the three species, and the genes involved in “RNA binding” to “Plasma membrane” and the genes involved in “Nucleus” to “Translation” between rice and yeast. Moreover, it was also shown that the two plant species share more conserved significant distribution correlations of the elements and gene function categories than those between rice and yeast, yeast and *A. thaliana*, and among the three species. These results suggest, at least in part, that the DNA “Jigsaw Puzzle” structures contained in more related species share more similarities in the content, array and interaction of the elements as well as genes. This is in accordance with the general consequence of natural selection in view of that more similar species share more similarities in biology, morphology and complexity in the course of species evolution. Although additional studies are needed to determine the relationships between the DNA “Jigsaw Puzzles” structure and organism biology, the observed distribution correlations between the genome fundamental function elements and genes with different functions have provided new,

useful information of the genomic element or gene network for plant and animal breeding.

Notes:

(1) RTE: Retro-transposable element; SSR: Simple repeat; LCR: Low complex repeat; GEN: Gene; TM: telomere maintenance; DNAB: DNA binding; TSFA: Transcription factor activity; RNAB: RNA binding; PB: Protein binding; NUS: Nucleus; CPM: Cytoplasm; PM: Plasma membrane; rRNAP: rRNA processing; TL: Translation; PAAP: Protein amino acid phosphorylation; RTS: Response to stress; RTDD: Response to DNA damage stimulus; EGT: ER to Golgi vesicle-mediated transport; EDCT: Endocytosis; CWOB: Cell wall organization and biogenesis; ST: Signal transduction; RBA: Ribosome biogenesis and assembly; RTD: Response to drug; PRT: Positive regulation of transcription from RNA polymerase II promoter.

(2) Differently highlighted colors of the χ^2 values indicate their significance levels: blue for a significance level of $p \leq 0.001$, green for a significance level of $p \leq 0.01$, and red for a significance level of $p \leq 0.05$.

Notes:

- (1) Scchr: *Saccharomyces cerevisiae* chromosome; GC: GC content; RTE: Retro-transposable element; SSR: Simple repeat; LCR: Low complex repeat; GEN: Gene.
- (2) The values of the correlation coefficient indicate the degree of correlation, ranging from 0.000 for no correlation to 1.000 for complete correlation. The positive values of correlation coefficients indicate the positive correlation between the element pair under comparison whereas the negative (-) values of correlation coefficients indicate the negative correlation between the element pair under comparison.
- (3) Differently highlighted colors indicate the significance levels of the distribution correlation between element pairs: blue for a significance level of $p \leq 0.001$, green for a significance level of $p \leq 0.01$, and red for a significance level of $p \leq 0.05$.

Table 17

Table 1. Spearman's correlation coefficients of distribution between genes categorized into different function categories in rice chromosome 5 with 500-kb windows

Notes:

(1) RP: Reproduction; NTB: Nucleotide binding; NAB: Nucleic acid binding; DNAB: DNA binding; CHRB: Chromatin binding; TCFA: Transcription factor activity; RNAB: RNA binding; CATA: catalytic activity; NUA: Nuclease activity; TPA: Transporter activity; PB: PCHRB: Chromatin binding; TCFA: Transcription factor activity; RNAB: RNA binding; CATA: catalytic activity; TL: Translation; PMP: Protein modification process; RTS: Response to stress; CC: Cell cycle; ST: Signal transduction; MOD: Multicellular organismal development; MT: Metabolism; CD: Cell death; CP: Catabolic process; BP: Biosynthesis process; stress; CC: Cell cycle; ST: Signal transduction; MOD: Multicellular organismal development; Photosynthesis; CCOB: Cellular component organization and biogenesis; CG: Cell growth; CDI: Cell differentiation; TCR: Transcription regulator activity.

(2) The values of the correlation coefficient indicate the degree of correlation, ranging from 0.000 for no correlation to 1.000 for complete correlation. The positive values of correlation coefficients indicate the positive correlation between the gene category pair under comparison. The signal "--" indicates that the correlation coefficient could not be calculated because one of the functional category pair had no genes along the chromosome or the whole genome after excluding the genes comparison. The signal "++" indicates

(3) Differently highlighted colors indicate the significance levels of the distribution correlation between gene category pairs: blue for a significance level of $p \leq 0.001$, green for a significance level of $p \leq 0.01$, and red for a significance level of $p \leq 0.05$.

Notes:

(1) TM: telomere maintenance; DNAB: DNA binding; TSFA: Transcription factor activity; RNAB: RNA binding; PB: Protein binding; NUS: Nucleus; CPM: Cytoplasm; PM: Plasma membrane; rRNAP: rRNA processing; TL: Translation; PAAP: Protein amino acid phosphorylation; RTS: Response to stress; RTDD: Response to DNA damage stimulus; EGT: ER to Golgi vesicle-mediated transport; EDCT: Endocytosis; CWOB: Cell wall organization and biogenesis; ST: Signal transduction; RBA: Ribosome biogenesis and assembly; RTD: Response to drug; PRT: Positive regulation of transcription from RNA polymerase II promoter.

(2) The values of the correlation coefficient indicate the degree of correlation, ranging from 0.000 for no correlation to 1.000 for complete correlation. The positive values of correlation coefficients indicate the positive correlation between the gene category pair under comparison whereas the negative (-) values of correlation coefficients indicate the negative correlation between the gene category pair under comparison. The symbol "--" indicates that the correlation coefficient could not be calculated because one of the gene categories had no genes along the chromosome after excluding the genes with both functions under comparison.

(3) Differently highlighted colors indicate the significance levels of the distribution correlation between gene category pairs: blue for a significance level of $p \leq 0.001$, green for a significance level of $p \leq 0.01$, and red for a significance level of $p \leq 0.05$.

Table 26
Spearman's correlation coefficients of distribution between fundamental function elements and genes with different functions in the whole rice genome with 500-kb windows

Notes:

(1) GC: GC content; RTE: Retro-transposable element; SSR: Simple repeat; LCR: Low complex repeat; GEN: Gene; TM: telomere maintenance; DNAB: DNA binding; TSFA: Transcription factor activity; RNAB: RNA binding; PB: Protein binding; NUS: Nucleus; CPM: Cytoplasm; PM: Plasma membrane; rRNAP: rRNA processing; TL: Translation; PAAP: Protein amino acid phosphorylation; RTS: Response to stress; RTDD: Response to DNA damage stimulus; EGT: ER to Golgi vesicle-mediated transport; EDCT: Endocytosis; CWOB: Cell wall organization and biogenesis; ST: Signal transduction; RBA: Ribosome biogenesis and assembly; RTD: Response to drug; PRT: Positive regulation of transcription from RNA polymerase II promoter.

(2) The values of the correlation coefficient indicate the degree of correlation, ranging from 0.000 for no correlation to 1.000 for complete correlation. The positive values of correlation coefficients indicate the positive correlation between the element/gene category pair under comparison whereas the negative (-) values of correlation coefficients indicate the negative correlation between the element/gene category pair under comparison.

(3) Differently highlighted colors indicate the significance levels of the distribution correlation between gene category pairs: blue for a significance level of $p \leq 0.001$, green for a significance level of $p \leq 0.01$, and red for a significance level of $p \leq 0.05$.
