ABSTRACT

Study of the Asphalt Pavement Damage through Nondestructive Testing on Overweight
Truck Routes. (May 2004)

Sonia Inés Ramos Aparicio, B.S., National
Engineering University, Lima, Peru

Chair of Advisor Committee: Dr. Robert L. Lytton

Many highway facilities experience deterioration due to high traffic volumes and a service life that has been extended beyond facility design life. The 75th and 76th Texas Legislatures passed bills allowing trucks of gross vehicle weights (GVW) up to 125,000 lbs to routinely use a route in south Texas. Since the Texas Department of Transportation (Tx DOT) is concerned about the impact of overweight truck traffic (OTT) on its highways, there is a need to establish how the impact of this OTT on Texas roads will be incorporated into a long-term strategy for identifying and developing solutions to this problem.

In this study the effects of overweight truck traffic was investigated on a permitted truck route in the city of Brownsville. This route proceeds from the Veterans International Bridge to the Port of Brownsville via US77, SH4 and SH48 (SH 4/48).

The objective of this study is to establish the impact of heavy loads on the pavement structure through nondestructive testing. The problem increased in severity due to the increased flow of trade from the Port of Brownsville to Mexico, thus the expecting deterioration on the routes is mainly along the southbound lanes K6 and K7.

To accomplish this objective two nondestructive testings were conducted as GPR and FWD tests. The K6 and K7 lanes were divided on 56 and 50 FWD stations, respectively. In addition, AC core samples were taken to be tested with frequency sweep test. All collected-data helped to analyze the route profile, layers thickness, static and dynamic backcalculated AC moduli, dynamic (complex) modulus from laboratory

testing, creep compliance parameters from the laboratory testing and dynamic analysis, and corrected AC moduli by temperature using three different equations. In addition, it analyzed the effect of the cumulative 18-kip Equivalent Single Axle (ESAL) in both K6 and K7 lanes.

The results from the first analysis provided evidence of damage in the K6 lane; however, more significant results were found in the traffic analysis. This study confirms that because of greater amount of truck traffic (OTT) travels on K6 has lesser AC moduli than the K7 lane.

DEDICATION

This thesis is dedicated to my family: Victoria and Floren my lovely parents, my aunt Juana, my brothers, my sister and Chris, who encourages me to pursuit my goal.

ACKNOWLEDGMENTS

I would like to express my sincere gratitude to Dr. Emmanuel Fernando, my Supervisor and Dr Robert Lytton , my advisor and chair of my committee, for their guidance and support during this research. Their creativity and engineering vision inspired me during the course of this thesis work. I also extend my appreciation to my other committee members, Dr. Dallas Little and Dr Michael Speed, for their comments on my research.

This research has been sponsored by the Texas Department of Transportation. I would like to express a special thanks to Joe Leidy, the Project Director, to Mr. Luis Carlos Peralez, from Pharr District, and Rene Castro, who made possible the FWD data collection and traffic control. In addition, I would like to extend my gratitude to Richard Peters, from Transportation Planning and Programming (TP&P) Division, who provided the weight-in-motion (WIM) data for fiscal year 2003 and Rhonda Christensen and Betty Hohensee who provided the lane distribution data at the WIM site along SH 4/48.

I would like to express my gratitude to Gerry Harrison and Lee Gustavus, research technicians, for their valuable support in the laboratory testing of this study.

Finally, I would like to express my gratitude to Lupe Fattorini, my colleagues, and anyone who assisted and encouraged me during the process of this research.

CHAPTER I

INTRODUCTION

Many highway facilities experience deterioration due to high traffic volumes and a service life that has been extended beyond facility design life. As aging road network conditions deteriorate, there is a need to increase investments and rehabilitation treatments in order to restore and maintain the road conditions at acceptable levels. The 75th and 76th Texas Legislatures passed bills allowing trucks of gross vehicle weights (GVW) up to 125,000 lbs to routinely use a route in south Texas, along the Mexican border. Since the Texas Department of Transportation (Tx DOT) is concerned about the impact of overweight truck traffic (OTT) on its highways, there is a need to establish how the impact of this OTT on Texas roads will be incorporated into a long-term strategy for identifying and developing solutions to this problem. These solutions could effectively promote future economic growth within the state Texas by preserving its highway infrastructures.

In this thesis was investigated the effects of overweight truck traffic on a permitted truck route in the city of Brownsville. This route proceeds from the Veterans International Bridge to the Port of Brownsville via US77, SH4 and SH48. The portion of the route along US77 is on a new concrete pavement and includes an elevated structure over half of its length. Most of the permitted truck route runs along SH4 and SH48. This research focused on studying the behaviour of the asphalt pavement supporting routine overweight truck traffic on SH4/48. Ninety-five percent of the truck traffic originates from the Port of Brownsville where the route starts at the FM 511 bridge, and runs along SH 48 until its intersection with Boca Chica Blvd. From there, truckers proceed along SH4 up to the US77 intersection, where they turn left to go to Mexico. Figure 1 gives an overview of the permitted truck route.

The thesis follows the style and format of the *Transportation Research Board*.

FIGURE 1 Permitted Truck Route in Brownsville SH 4/48.

The payloads carried by permitted trucks are mostly coiled metal sheets, oil, and powder mineral (fluorite), which are transported from the Port of Brownsville to Mexico and vice versa. Figure 2 illustrates the types of payloads transported along the permitted truck route. The route was established in response to the need expressed by truckers to haul cargo at their trucks' operating capacities to improve operational efficiency. This meant hauling in excess of legal load limits, thus requiring permits to be issued.

The permit fee is US \$30 per one-way trip. Even though the Pharr District retains 85% of the permit fee, it is too small an amount to cover the route's maintenance because of the potential for accelerated pavement deterioration. Therefore, it is relevant to study the effects of these routine overweight loads that run on SH 4/48 in order to identify requirements for building pavements to sustain routine overweight truck traffic. This information could help in maximizing trucking productivity and in enhancing the economic competitiveness of the state.

OBJECTIVES

The primary objectives of this research are to:

- characterize the effects of routine overweight truck loads on the performance of SH 4/48; and
- establish the impact of heavy truck loads on pavement performance.

These objectives were accomplished by carrying out nondestructive pavement testing, laboratory materials testing, evaluation of material properties from field and laboratory test data, and modeling of pavement response. The expected benefits from this study are recommendations regarding an analysis procedure to determine the feasibility of using existing routes for overweight truck traffic. This project offered the first opportunity to study the effects of OTT on Texas highways. The data collected from this research are expected to be useful in establishing and developing ways to achieve the best accommodation of increased truck use on Texas highways.

FIGURE 2 Types of Loads Carried by Permitted Trucks.

PROBLEM STATEMENT

The nature of this complex problem can be stated as follows:

- the initial design for this route was based on conventional truck traffic conforming to legal load limits. Routine use of SH4/48 by overweight trucks began in March 1998.
- the problem increased in severity due to the increased flow of trade from the Port of Brownsville to Mexico. The deterioration on the routes is mainly along the southbound lanes K6 and K7.
- the impact of overweight truck traffic is a concern because the service life of highways under these conditions is unknown.

SCOPE OF THE RESEARCH

This thesis is documented in nine chapters. Chapter 1 is the introductory Chapter that gives the impetus for this study. Chapter II describes the concepts involved in the nondestructive test methods used to evaluate the effects of routine overweight truck traffic on SH4/48. Chapter III details the field data and laboratory testing methodology. It also describes how the SH4/48 route was segmented into different sections on the K6 and K7 lanes for the purpose of field data collection. The Chapter also identifies the locations (FWD stations) where cores were taken for laboratory testing. These FWD stations are named “core stations” in this study. Chapter IV summarizes the results of the analyses of the field data collected during the project. The field data taken with the falling weight deflectometer (FWD) and ground penetrating radar (GPR) are analyzed in this Chapter in order to predict pavement layer thickness profiles and static layer moduli values. Chapter V reports on the analysis of FWD data to characterize the dynamic modulus and the creep compliance properties of the asphalt concrete layer using dynamic analysis. The dynamic moduli backcalculated by system identification are compared to the backcalculated moduli from the static analysis. The dynamic analysis of full-time FWD data was conducted using the Dynamic Backcalculation by System Identification (DBSID) program developed by the Texas Transportation Institute (TTI). Static backcalculations were performed using MODULUS.

Chapter VI presents the results of laboratory tests of the field cores taken from SH4/48. The test carried out to characterize the asphalt layer was the frequency sweep test. Chapter VII presents the temperature corrections of backcalculated moduli beginning with the pavement temperature predictions. It was examined the corrected moduli as well as the modulus-temperature relationships determined from the test data as part of assessing the pavement damage along the route. For this analysis, the FWD stations on the K6 and K7 lanes were grouped, taking into consideration their values and the stations' proximity to each other. The temperature corrections of backcalculated moduli were done using three methods: the Chen equation, the TxDOT equation, and the Wiczak-Fonseca equation.

Chapter VIII discusses the comparison between the results obtained from field data presented in Chapters IV and V, and the laboratory data presented in Chapter VI. In addition, this Chapter takes the results obtained from the Witzak-Fonseca equation in order to show the current damage to the different sections along the route. Chapter IX summarizes the conclusions and recommendations stemming from this study.

CHAPTER II

LITERATURE REVIEW

This chapter presents relevant information regarding the test methods used to characterize the effects of permitted overweight loads on SH4/48.

GPR APPLICATIONS

Applying GPR techniques for nondestructive testing on highways and bridge decks has become more common in recent years. GPR has been demonstrated to be an accurate and practical tool for nondestructive evaluation and inspection of highway structures. Different types of radar may be used for different applications on highway pavements. Depending on the way they operate, radar falls into two categories: air-launched and ground-coupled.

Air-launched GPR operates with the antenna mounted at a specific height perpendicular to the pavement surface. This type of GPR is ideal for highway speed data collection, since there is no contact between the pavement surface and the antenna (1).

Ground-coupled GPR operates with its planar antennas in close contact with the pavement. This contact allows a better horizontal resolution, in the direction of the survey motion. This antenna is particularly suited to investigating defects in concrete pavements and bridge decks. The drawback is its data acquisition speed, which is limited to less than 6 mph. Defects such as surface cracks, voids, etc., or those of with relative profundity, one meter below the surface, can sometimes be detected with low frequency ground-coupled radar.

Air-launched radar systems work at the central frequency of approximately 1 GHz, while most ground-coupled radar systems work at lower frequencies, typically from 20 to 500 MHz (2). The lower the frequency, the greater the penetration depth, but those lower frequencies offer less in near-surface resolution. For instance, under similar soil conditions, 100 MHz antennas may provide subsurface information to depths of 50 ft.

However, they will not be able to identify the presence of thin surface layers. On the other hand, a high frequency ground-coupled systems may only penetrate to a depth of 3 ft, but it can identify thin layers close to the surface. The Texas Transportation Institute's air-launched GPR unit operates at highway speeds (60 mph), and transmits and receives 50 pulses per second. It can effectively penetrate to a depth of two feet.

For the practical implementation of a GPR system, an automated signal processing is needed so that the mass of waveforms collected in a GPR survey can be transformed into information meaningful to highway engineers. In the past, TTI researchers used a signal processing system named DACQ to analyze GPR data (3). Its main feature is an automated peak tracking system, in which the user identifies significant peaks within the GPR trace. The software then automatically traces those peaks throughout the entire file (3). For each peak, the amplitudes and arrival times ~~was~~ of reflections were determined from the GPR data and used to compute the layer dielectrics and thicknesses. Other advanced features of DACQ is a correction procedure for antenna bounce, and several signal clean-up routines, which are applied prior to processing. However, there were several drawbacks with DACQ such as slow data processing if long lengths of highway were to be processed. Additionally, it was difficult to identify section breaks and the peak tracking system was difficult to use on several projects with badly distressed pavements..

Because of these limitations, a new processing package was subsequently developed to match Tx DOT's needs more closely. These needs are the capability of rapidly evaluating long sections of highway, of defining section changes, estimating layer thickness, and locating subsurface problem areas. COLORMAP is the software package that succeeded DACQ (4). It was developed to provide a simple program that non-GPR experts can easily understand and use to interpret GPR data for pavement evaluation. In order to evaluate massive amounts of data in a timely fashion, COLORMAP employs several innovative data processing techniques. It relies on a color graphics display of GPR data to identify breaks and surface problems, and the manual tracking of layer interfaces in the layer computation routine.

FALLING WEIGHT DEFLECTOMETER

A nondestructive test is one from which the necessary information can be obtained to define physical properties of a sample without destroying it. In pavement evaluation, this involves a large mechanical device to duplicate vehicle loads without breaking up the pavement. By measuring the pavement response induced by loads, the structural integrity or stress-strain properties of the pavement structure can be determined (5).

The FWD is an impulse device used in the nondestructive testing of pavements because it reasonably simulates the shape and temporal nature of a moving wheel loading (5). In addition, during FWD tests, the pavement's stress and strain conditions are similar to the conditions under a heavy vehicle load (6). The major advantages of FWD testing are that:

- The impulse dropweight force on the pavement simulates traffic loads at highway speed.
- It is nondestructive.
- Pavement layer materials remain undisturbed.
- AC creep compliance data can be computed from FWD full-time history data and dynamic analysis. Pavement cracking and rutting can then be predicted from the creep compliance properties.

FWD is used in pavement evaluations to estimate pavement layer moduli for predicting remaining life. Most backcalculation procedures currently implemented predict the layer moduli from the peak load and the peak deflections measured by geophones. In this analysis, it is assumed that the FWD load is applied statically to the pavement, which is represented as an elastic layered system with linear or non linear (stress-dependent) material properties. These properties are backcalculated by minimizing the sum of the absolute or square of the errors between the predicted and the measured peak deflections at the geophone locations.

FWD works by applying an impulse load to the pavement which generates body waves and surface waves (7). These waves travel at finite velocities and are recorded at different times by the geophones. The time lag of the response of the geophones is determined by transforming the load and the deflection histories from the time domain to the frequency domain by using the fast Fourier transform (FFT) method. Then, the FFT of the deflection history is divided by the FFT of the load history in order to obtain the pavement system transfer function. The magnitude of the deflection per unit force and the phase angle are then determined, frequency by frequency.

The layered elastic backcalculation program MODULUS 6.0 (8) developed by TTI, was used to analyze the FWD deflection data, specifically, to backcalculate layer moduli at different locations along the permitted truck route.

DYNAMIC ANALYSIS OF FWD DATA FOR PAVEMENT EVALUATION

Lytton (7) explained that there are more information in the FWD data than load and displacement amplitudes, and showed how other properties may be backcalculated using the load and displacement histories from the FWD. These properties include the creep compliance coefficients that may be determined from the analysis of the FWD load and deflection time histories:

$$D(t) = D_o + D_1 t^m \quad (2.1)$$

where,

$D(t)$ = creep compliance at loading time t ,

D_o , D_1 and m = coefficients of the power law model given by Eq. (2.1).

The slope m of the log creep compliance vs log time curve is directly related to the material damping as characterized by the phase angle.

There are several computer programs used to analyze the full time history data. These programs predict the transfer function or the FWD displacement history for each sensor. Among them are PUNCH (9), UTFWIBM (10), SCALPOT (11), and FWD-DYN

(12). The first three methods predict the transfer function and the fourth, FWD-DYN, predicts the displacement history for a given sensor and pavement.

The FWD-DYN predicts the displacement history for each sensor, given the material properties and thickness of each pavement layer. In this program, the FWD load is first decomposed into its frequency components using FFT. Then, the transfer function, which defines the response of the pavement system to a steady-state unit load, is evaluated. Finally, the transfer function is multiplied by the FFT of the load to determine the Fourier transform of the displacement time history. FWD-DYN performs an inverse FFT on this Fourier transform to determine the time history of the displacement for each FWD sensor. It is significant to point out that the procedure assumes a linear system in view of the use of superposition to predict pavement response to the impulse load (13).

The computer program DBSID determines the material properties using FWD data and full time load and displacement histories. DBSID was the result of adding a system identification routine to the FWD-DYN program. In this computer program, the pavement structure is limited to three layers of pavement, the first layer (AC) being a viscoelastic material following the power law creep compliance relationship of Eq. (2.1). The other two unbound layers are modeled as damped elastic solids characterized by Young's modulus and the damping coefficient. The equations to backcalculate the creep compliance parameters of Eq. (2.1) represent the relationship between the complex compliance and the complex modulus, and are given by Lytton (7).

$$D'(\omega) = D_o + D_1 \frac{\Gamma(1+m)}{\omega^m} \cos\left[\frac{\pi m}{2}\right] \quad (2.2)$$

$$D''(\omega) = D_1 \frac{\Gamma(1+m)}{\omega^m} \sin\left[\frac{\pi m}{2}\right] \quad (2.3)$$

$$E'(\omega) = \frac{D'(\omega)}{\left[D'(\omega)^2 + D''(\omega)^2\right]^{\frac{1}{2}}} \quad (2.4)$$

$$E'(\omega) = \frac{D''(\omega)}{\left[D'(\omega)^2 + D''(\omega)^2 \right]^{\frac{1}{2}}} \quad (2.5)$$

$$\zeta(\omega) = \frac{E''(\omega)}{2E'(\omega)} \quad (2.6)$$

where,

- $D'(\omega)$ = real part of the complex compliance,
- $D''(\omega)$ = imaginary part of the complex compliance,
- $E'(\omega)$ = real part of the complex modulus,
- $E''(\omega)$ = imaginary part of the complex modulus,
- $\zeta(\omega)$ = damping ratio,
- $\Gamma(1+m)$ = gamma function with parameter $(1+m)$, and
- ω = loading frequency, radians/sec.

TEMPERATURE CORRECTIONS OF BACKCALCULATED AC MODULUS

The use of surface deflection measurements to evaluate pavements has steadily increased in the majority of highway agencies since the American Association of State Highway Officials (AASHO) road test was conducted. Deflection testing is used to evaluate a variety of pavement characteristics, including axle or vehicle load capacity, structural life, and uniformity. Deflection results are dependent upon seasonal variations that are affected by the underlying aggregate base course and subgrade. It is more significant in asphalt pavements which are dependent on the temperature of the asphalt (14). In fact, those factors that influence deflections are loading, environment, and pavement conditions. The environmental conditions related to seasonal variations are the temperature and moisture distributions within and around the pavement structures. The importance of these major factors is that they change the strength of the pavement materials and their resistance to traffic-induced stresses.

For pavement applications, the asphalt concrete moduli backcalculated from FWD data must be corrected to reference or standard conditions of temperature and loading

frequency. Before the temperature correction may be made, it is first necessary to determine the pavement temperature one is correcting from. This temperature is referred to herein as the base temperature, and correspond to the pavement temperature when the FWD data were collected. For this purpose, pavement temperatures may be measured directly with a temperature probe, or predicted from measured air and surface temperatures. In this regard, Lukanen (*14*) developed a set of equations for predicting pavement temperatures. These equations, referred to in the literature as BELLS2 and BELLS3, were developed using pavement temperature data from 41 Seasonal Monitoring Program (SMP) sites in North America.

BELLS2 is the equation used for the FWD testing protocol employed in the Long-Term Pavement Performance (LTPP) program, while BELLS3 is used for routine testing. The latter was developed to account for the effects of shading on the infrared temperatures measured at the SMP sites. Both equations require use of the infrared (IR) surface temperature at the time of the FWD measurements, and the average of the previous day's minimum and maximum air temperatures in the area of the project surveyed. The BELLS2 and BELLS3 equations have the following form and are different only in the coefficients β_i :

$$T_d = \beta_0 + \beta_1 IR + [\log_{10}(d) - 1.25][\beta_2 IR + \beta_3 T_{(1\text{-day})} + \beta_4 \sin(\text{hr}_{18} - 15.5)] + \beta_3 IR \sin(\text{hr}_{18} - 13.5) \quad (2.7)$$

where,

- T_d = pavement temperature at depth, d (mm), within the asphalt layer in $^{\circ}\text{C}$,
- IR = surface temperature measured with the infrared temperature gauge in $^{\circ}\text{C}$,
- $T_{(1\text{-day})}$ = the average of the previous day's high and low air temperature in $^{\circ}\text{C}$,

- hr_{18} = time of day in the 24-hour system, but calculated using an 18-hour asphalt temperature rise and fall time according to Stubstad (15),
- β_i = coefficients of Eq. (2.7), which are given in Table 1 for both the BELLS2 and BELLS3 equations.

In TxDOT Project 0-1863, (16) TTI researchers developed an alternative equation, named the Texas-LTPP equation, which is considered more applicable for use in Texas. This equation is given by :

$$T_d = \beta_0 + \beta_1 (IR+2)^{1.5} + \log_{10}(d) \times \{ \beta_2 (IR+2)^{1.5} + \beta_3 \sin^2(hr_{18} - 15.5) + \beta_4 \sin^2(hr_{18} - 13.5) + \beta_5 [T_{(1\text{-day})} + 6]^{1.5} \} + \beta_6 \sin^2(hr_{18} - 15.5) \sin^2(hr_{18} - 13.5) \quad (2.8)$$

The coefficients, β_i , of Eq. (2.8) were determined using multiple linear regression with measured IR and pavement temperature data from the asphalt concrete SMP sites in Texas, New Mexico, and Oklahoma, and from asphalt sections located at the Texas A&M Riverside Campus. Table 2 presents the coefficients of the Texas –LTPP equation. The interested reader is referred to Fernando, Liu and Ryu (16) for additional details on the development of this equation. Comparing the predictions of the BELLS2, calibrated BELLS2, and the Texas-LTPP equations, these researchers found that the most accurate predictions for Texas conditions are obtained using the Texas-LTPP equation.

Project 0-1863 led to the development of the TxDOT Modulus Temperature Correction Program (MTCP), which may be used to correct asphalt concrete moduli backcalculated from FWD data to reference or standard conditions of temperature and loading frequency (17). MTCP provides users with the option of using BELLS2, BELLS3, or the Texas-LTPP equation for predicting pavement temperature. The program uses the output from MODULUS as an input to the modulus temperature correction.

CHAPTER III

FIELD DATA COLLECTION

The field data collection on SH4/48 involved the following tasks:

- An initial site investigation,
- Establishing FWD monitoring sections,
- Material sampling.

This chapter documents the tasks carried out to collect data for characterizing the effects of overweight truck traffic on SH4/48 in Brownsville.

INITIAL SITE OF INVESTIGATION

The main objective of the initial site investigation was to collect information that may be used to establish test segments for field monitoring. For this purpose, the following tasks were conducted:

- Ground penetrating radar measurements along SH4/48;
- Identification of homogeneous segments from GPR surveys according to the predicted layer thickness profiles;
- Selection of FWD stations on each homogeneous segment;
- Prediction of layer thicknesses of the asphalt and flexible base materials; and
- Core sampling to verify GPR predictions, assist in data interpretation, and provide cores for laboratory testing.

It began with inputting a name for of different lanes of the route in both directions. The route lanes that run from Mexico to the Port of Brownsville, northbound, were called K1 and K2, which were the outside and inside lanes, respectively. In the same way the route lanes which run from the Port of Brownsville to Mexico, southbound, were named K6, the outside lane and K7, the inside lane.

Two GPR surveys were conducted to estimate the pavement layer thickness profiles along SH4/48 as first tasks. The first survey, conducted in September 2000, was done using TxDOT's air-launched GPR system. From the data collected was predicted

the surface layer thickness variations along SH4/48. However, information on the layering beneath the surface material was difficult to get, as the reflections coming after the surface layer were either not visible or very faint. Consequently, it was conducted another survey in February 2001, using ground-coupled radar antennas manufactured by Geophysical Survey Systems Incorporated (GSSI). This second survey was conducted along the outside and inside southbound lanes of SH4/48 corresponding, respectively, to the K6 and K7 lanes of the permitted truck route. Since most of the permitted trucks (about 95 percent) travel from the Port of Brownsville to Mexico, the decision was made to monitor these lanes during the project.

Two ground-coupled radar antennas were used. One was a GSSI 200 MHz unit that was primarily used to check the depth of the water table along the route. The other was a 1.5 GHz antenna that it was used to collect data on the near-surface pavement layers. Figure 3 shows the ground-coupled antennas used by researchers. Data from the 1.5 GHz antenna, along with coring information taken at various locations, were used to establish the base layer thickness profiles along the K6 and K7 lanes. It was not possible to see the ground water table from the GPR data collected with the 200 MHz antenna. Researchers note that Pharr District personnel drilled a hole on the shoulder near the location of a weigh-in-motion (WIM) site along SH48. No water table was encountered to a depth of 13 ft from the pavement surface at this location.

ESTABLISHING FWD MONITORING STATIONS

Based on the GPR measurements, it was established FWD stations along the K6 and K7 lanes of the permitted truck route. The portion of the route monitored in this study begins at the FM511 and SH48 intersection and ends approximately 0.14 miles south of Cleveland Street along SH4. The K6 lane was segmented into 16 homogeneous sections (A to P), while the K7 lane was divided into 6 homogeneous sections (A to F). Tables 3 and 4 summarize the locations of the different sections established, respectively, on the K6 and K7 lanes. The locations of the section endpoints are referred to the south end of the bridge over FM511.

Once the homogeneous sections in each lane were defined, researchers established the locations of the FWD stations in each section. Altogether, there were 56 FWD stations established on the K6 lane, and 50 stations on the K7 lane. Tables 5 and 6 show the locations of the FWD stations on which data were collected at different times during the project. In this regard, personnel from the Pharr District provided FWD data for evaluating and monitoring pavement performance along the K6 and K7 lanes.

According to the initial GPR survey in Appendix A was detected variations on the asphalt concrete (AC) thickness and the possibility of the stripping layers. The extreme cases of AC thickness variation are seen in the sections K6-H, K6-I, K6-K, K7-C and K7-E. Possible stripping layers are seen in the sections K6-L and at some points in sections K7-E. Consequent to these possible issues, each section of the lanes K6 and K7 were divided into homogeneous sub-segments. The FWD stations were chosen from these sub-segments.

In COLORMAP Figures 4 to 23 the location of all FWD stations for lanes both K6 and K7 are indicated. Each trace marker indicates the respective FWD station.

The average distance between two consecutive stations is approximately 152 m (500 feet). These stations were selected on the asphalt pavement, skipping the FM 511 (bridge), and the intersection FM 802 and Central Ave and the intersection between Boca Chica Blvd. with SH 48.

To locate the FWD stations, the distance measured between them were referred to the center of the street intersections or culverts. The streets used as references were the FM 511-bridge, FM 802, Minnesota Ave, Central Ave, Fruitdale Rd, Price Rd, Intersection SH4/SH48, Security Dr., Southmost Rd and Cleveland St

In this study, FWD data were monitored from February of 2001 to April of 2003 through intervals between four and seven months. In 2001, FWD data were collected in February, May, July and August; in 2002 in March, July, October and December, and in 2003, data was collected only in April. FWD data was taken in K6 lane four times in 2001: in February, May, July and August; and three times in 2002: in March, July and December. FWD data were collected in K7 lane three times in 2001: in February, May and August; four times in 2002: in March, July, October and December; and once in April of 2003.

In addition, the FWD stations K6-9, K7-8 and K7-9 were removed and no longer used after March of 2002 due to construction work on the road. There were other FWD stations which were omitted once in the FWD data collection because of road

maintenance or construction work. They were K6-8 in March of 2002, K6-33 in July of 2002, K7-11, K7-12 and K7-22 in October of 2002 and K7-43 in April of 2003.

MATERIAL SAMPLING

For GPR data interpretation and verification, a total of 20 cores were initially taken from SH4/48, 10 samples in each of the K6 and K7 lanes. Tables 7 and 8 show the locations where cores were taken. At these locations, the coring crew also measured the base thickness. The measured base thicknesses at the coring locations are also given in Tables 7 and 8.

During coring, a number of the six-inch diameter cores broke. These occurred in the downtown area along SH4, where difficulty was encountered in getting intact cores. Disintegration of the asphalt material during coring suggested possible stripping within the mix. In order to get additional cores for laboratory testing, Pharr District personnel took several more cores from the K6 lane along SH4, specifically at FWD stations K6-48,

K6-50, K6-51, and K6-53. This time, three-inch diameter cores were taken. Table 9 shows the thicknesses of the additional cores.

In addition, a set of five cores were taken at the WIM site along SH48. These are identified as C2 to C6 in Table 9. C2 and C3 were taken from the wheelpaths of the K6 lane, while C4 and C5 were taken from the K7 lane. C6 was taken from the center lane along SH48, which receives very little traffic at the vicinity of the WIM site.

CHAPTER IV

STATIC ANALYSIS

ANALYSIS OF THE LAYER THICKNESS

As was explained in Chapter III, TTI conducted a two GPR survey with a Ground-Coupled Antenna (200 MHz) and another GPR survey with an Air-launched Antenna (1.5GHz) on the SH 4/48 in Brownsville, Texas. This study was conducted for both lanes K6 and K7, covering 106 FWD stations.

The data processing, positioning and interpretations of these measurements were done by Roadscanner Oy which analyzed the data using Road Doctor™ software. The processing methods were the static background removal, signal amplification and horizontal and vertical filtering. Roadscanner Oy reported the layer thickness of the AC and the flexible base course after verifying with the thickness of the cores. Because the FWD stations are located at approximately 150 m (500 feet) spacing and Roadscanner Oy made the analysis of layer thickness every foot the average layer thickness was calculated for each 100 feet. Tables 10 and 11 show the predicted thicknesses reported by Roadscanners Oy, the average thickness and standard deviation calculated by +/- 50 feet of FWD stations.

The thicknesses of the AC and the flexible base (FB) for both lanes were plotted and can be seen in Figures 24, 25, 26 for the K6 lane, and 27, 28 and 29 for the K7 lane. These charts show four significant points, upon which it is necessary to remark: first, the thickness calculated by Roadscanner Oy; second, the average thickness; third, the core thickness taken in the initial 20 FWD stations; and finally, the layer thickness at each FWD station. It should be noted that there are more variations of AC thickness in the K6 lane than in the K7 lane, as seen in Figures 25 and 27. In addition, in both lanes, the AC thicknesses increase and the FB thicknesses decrease in the downtown area, as seen in Figures 24 and 29.

ANALYSIS OF THE LAYER MODULI

As it was stated previously, FWD data was collected seven different times during three years: 2001, 2002, and 2003. The MODULUS 6.0 software (18) was used for the determination of moduli values. Due to the apparent thickness variations along the K6 lane, the backcalculated modulus was done by station using the predicted thickness from Tables 10 and 11. Several trials have been made to adjust the backcalculated modulus beginning with the predicted thickness. Figure 30 gives the initial idea about the pavement structural layers used to determine the backcalculated moduli. They are asphalt concrete (AC), flexible base (FB), and subgrade (SG). Unfortunately, the first attempt had a high error rate between the measured and predicted deflections more than 10% in all the downtown stations in the K6 lane, from K6-42 up to K6-56. In addition, in some of the stations such as K6-11, K6-33, K7 -31 the backcalculated moduli did not have variations over time. It means that they did not show any time-temperature relationships. Therefore, it was evaluated different ways of modeling the pavement materials underlying the AC surface.

Legend Layer Thickness

FIGURE 30 Initially Assumed Pavement Structure Layers.

The next attempts at reducing the error rate were made by combining the flexible base predicted thickness with lower layer thicknesses such as the salvaged flexible base (Salv.) and treated limestone (LT). This gave a new flexible base thickness (NFB). These lower layer thicknesses were checked out in the field, at the K6-4 FWD station as seen in Figure 31, and with the maintenance records of the Pharr District. The representation of

the pavement layering for modulus backcalculation resulting in lower errors is shown in the Figure 32.

Since the backcalculated modulus is determined by station using the predicted thickness from Tables 10 and 11, the thickness values that appear on the Figures 30, 31 and 32 are only approximated.

FIGURE 31 Pavement Structure Thickness in the K6-4 FWD Station.

FIGURE 32 Pavement Structure Layers Used in Backcalculated Modulus.

The backcalculated modulus has been plotted vs. time by station. This means that the AC, NFB and SG moduli can be seen in same plot in the bar chart. Appendix B shows all these plots for both lanes K6 and K7. Tables 12 and 13 indicate the percentage of error in backcalculated modulus found in these analyses.

CHAPTER V

DYNAMIC ANALYSIS

DYNAMIC MODULUS AND CREEP COMPLIANCE PARAMETERS

For the dynamic analysis the computer program DBSID was used, (18). This program uses the FWD full time histories of load and displacement for the backcalculation of pavement material properties. This program permits the simulation of a pavement layer structure consisting of up to three layers. The consideration taken for this analysis was that the first layer (AC) is modeled as a viscoelastic material and the second layer (flexible base) and third layer (subgrade) as damped elastic material. Since the maximum iteration number of DBSID is 40 iterations, there is a variety of results that may be analyzed. These results were analyzed by two criteria: by plotting the measured and predicted displacement history data and by the root mean square error (RMSE) of deflections of each iteration.

Even though there is a significant amount data to process in dynamic analysis, in this study, only the core stations were analyzed. These FWD stations are K6-1 K6-4, K6-11, K6-23, K6-29, K6-35, K6-48, K7-3, K7-11, K7-20, K7-31, K7-37 and K7-40. The stations K6-50, K6-51 and K6-53 were omitted because they did not give clear results in the laboratory testing. In addition, K7-9 was not analyzed due to the fact that FWD data was stopped due to construction that resulted in a change of pavement at this station.

In Appendix C one may see the plots of the measured and predicted displacement histories by the FWD stations and the time corresponding to both the K6 and K7 lanes. These plots show that the predicted measurement fit the measured values quite adequately in most of the FWD stations. However, there were some FWD stations that did not provide a good results in dynamic analysis, such as K7-3 during any months, K6-1 and K6-4 in the month of February of 2001, and K6-35 in May and August of 2001, March, July and August of 2002.

In addition, Tables 14 to 26 present the creep compliance parameters, layer modulus, depth to a rigid layer (DB), and RMSE in the predicted deflections by station and time.

In Chapter VIII the backcalculated AC modulus obtained from dynamic analysis will be discussed and compared to those from static analysis. In addition, the correlation between the creep compliance parameters from the dynamic analysis and laboratory testing will be analyzed.

CHAPTER VI

LABORATORY TESTING

The main purpose of laboratory testing is to get helpful information about the changes in the AC layer of the pavement as it is affected by routine overweight truck traffic. Due to the fact that AC undergoes time-dependent changes, it is significant to consider this condition in material characterizations. According to the AASHTO 2002 Design Guide (19), the long-term, time-dependent property changes come about because of one of these conditions: the chemical and physical hardening of the asphalt binder due to short or long-term aging of the AC binder, curing caused by evaporation of the moisture inside of asphalt emulsion system, and pozzuolanic reactions of cementitious materials.

In addition, the 2002 Design Guide (19) indicates that materials subjected to load-related fatigue distress may undergo a severe degradation of properties with time and load repetitions. Microcracks may develop, leading to a reduced modulus. The possible reduction of modulus due to this, would lead to an increase in a stress and larger possibility of permanent deformation.

DYNAMIC MODULUS OF THE ASPHALT CONCRETE MIXTURE /E*/

The standard tests in the NCHRP 1-37 DM1 Draft Standard Test Method for the Dynamic Modulus of Asphalt Concrete Mixtures ASU May –2002 (20), and ASTM D3497-79, Standard Test Method for Dynamic Modulus of Asphalt Mixtures (21) cover procedures for preparing and testing to determine the dynamic modulus and phase angle over a range of temperature and loading frequencies. Both tests are carried out by applying a sinusoidal (haversine) axial compression stress to the asphalt concrete sample at a given temperature and loading frequency. The applied stress and recoverable axial strain response of the samples are measured to calculate the dynamic modulus and phase angle. The method produces results that differ with the frequencies and temperatures used

in the testing. While ASTM D3497-79 (21) uses temperatures such as 5, 25 and 40 °C with frequencies of 1, 4 and 16 Hz, the NCHRP 1-37 (20) has a greater range of temperatures and frequencies used, such as -10, 4, 20, 37.8 and 54.4 °C, and 25, 10, 5, 1, 0.5 and 0.1 Hz, respectively.

On the other hand, the number of replications indicated by ASTM D3497-79 is 6 samples of the pavement cores, while the NCHRP 1-37 is limited to 4 specimens if it is used with two LVDTs per specimen. Therefore, with the purpose of getting the best simulation of the field's AC properties the NCHRP 1-37 standard was selected to determine the dynamic (complex) modulus of the AC cores.

It is known that the temperatures in the city of Brownsville do not drop a grade below zero during the winter season. In addition, since the laboratory testing was begun during Summer of 2002 and the only pavement temperatures from the FWD data available by that time, as seen in Table 27, reflect that the pavement temperature at 25.4 mm (1 in) or predicted pavement temperature at middle depth had a range between 21.1°C and 54.4°C (70 °F and 130 °F). Consequently, the temperatures used in the test were six: 21.1, 29.4, 37.8, 43.3 and 54.4 °C (70, 85, 100, 110 and 130 °C).

* No data.

As was mentioned in Chapter II the number of AC cores taken initially were reduced by handling or breaking problems. The final number of tested cores were 12 cores for the lane K6, and 9 for the lane K7, and an additional 4 samples collected in the vicinity of the K6-4 FWD station. Tables 28, 29 and 30 specify core measurements from the laboratory testing. Even though in the NCHRP 1-37 standard specifies that the dynamic modulus testing ought to be tested on cores with nominal diameters of 101,6 mm (4 in), the second set of samples taken in the downtown area were cored with smaller diameters due to their lower stiffness. It is significant that the cores did not have a homogenous AC material with height (thickness). For that reason the position of the linear variable differential transformer (LVDT) clamps were set up 25mm (1”) from the top and the bottom ends of the surface cores. The LVDT gauge length (GL) that was employed on the tested cores is detailed in Figure 33.

The set of frequencies and number of cycles used were those indicated in the selected standard. They are 25, 10, 5, 1, 0.1 and 0.5 Hz, and with 200, 200, 100, 20, 15, and 15 cycles, respectively. Before cores could be tested, they were placed in the environmental chamber to equilibrate them to the required temperature. The specimen C2 was used as a dummy specimen in the preparation of this test.

FIGURE 33 Location of the LVDTs at the AC Cores.

The laboratory data were processed by computer program to get complex modulus (E^*) and creep compliance (D) with their corresponding real and imaginary parts. The dynamic complex modulus ($|E^*|$) is got from the absolute value of the complex modulus.

The calculations of the angle phase (ϕ)

$$\phi = (t_i / t_p) \times 360$$

were determined from max (min) points and not from the mid point values. Figure 34 shows the time lag (t_i) and loading cycle period (t_p) used.

All of these properties (E^* , D and δ) were calculated with four approaches named Case 1, Case 2, Case 3, and Case 4.

- Case 1: The amplitude of the load and deformation were from regression data and the angle phase was calculated from the regression at minimum points.
- Case 2: The amplitude of the load and deformation were from raw data and the angle phase was from the regression at minimum points.
- Case 3: The amplitude of the load and deformation were from regression data and the angle phase was from the regression at maximum points.
- Case 4: The amplitude of the load and deformation were from raw data and the angle phase was from the regression at maximum points.

Appendix D shows all of the possible combinations (a max 12 combinations in each testing temperature) necessary to get the curves of the dynamic modulus at different frequencies. Figures 35 to 49 present the best results in each tested core.

CREEP COMPLIANCE PARAMETERS

Due to the fact that the creep compliance (D) is a complex number defined as the inverse of the complex modulus (E^*) for a linear viscoelastic material (22) whose values, real and imaginary, were calculated with the computer program indicated before; then, it is possible to backcalculate the parameters of the creep compliance as defined in equations 2.1, 2.2 and 2.3. Tables 31 to 41 give the predicted creep compliance parameters, D_0 , D_1 and “ m ”, based upon values obtained from computer analysis of laboratory data. These tables also mention the Sum of Square Error (SSE) of each data set calculated. Even though all core stations were performed by computer programs to obtain the creep compliance parameters, some stations such as K6-29, K6-35, K7-3 and K7-9 could not get valid “ m ” values. The criteria to select valid “ m ” values was that the “ m ” values should increase as the temperature increases.

However, most “ m ” values of core stations fall at the higher temperature 54.4 °C (130 °F) for both the K6 and the K7 lane.

CHAPTER VII

TEMPERATURE CORRECTION OF BACKCALCULATED MODULUS

PREDICTION OF PAVEMENT TEMPERATURES

Before conducting the temperature correction of the backcalculated modulus it was necessary to set up which pavement temperatures would be used in this correction. This pavement temperature is based on the temperatures taken from the FWD collected data, which could be taken by direct measurements with a temperature probe or from predictive methods based on air and surface temperatures.

In the FWD survey, the operator took the surface pavement temperature at each station and the air temperatures were directly set up in the system of the FWD data. The pavement temperature was taken at 25 mm of depth below the AC surface, and was collected at every ten stations, from the first to the last FWD stations of each lane.

In TTI Research Report 1863-1 was developed software that assists in the prediction of pavement temperatures at different depths, Modulus Temperature Correction Program (MTCP) (17), (18). MTCP was utilized in this study to predict the pavement temperatures. MTCP uses the infrared surface temperature and the previous day's average air temperature to predict the pavement temperature at given depth, d .

The depth from the surface employed in this study, to predict pavement temperatures, was at the middle of the AC thickness. The surface pavement temperature was measured with a calibrated infrared surface temperature gauge and the previous day's average air temperature was found through the Texas Office of State Climatologist of the Texas A&M University.

To get a prediction of the pavement temperature, the MTCP should select one of three equations: the BELLS2, the BELLS3 and the Texas-LTPP. According to recommendations by the TTI Research Report 1863-1, the Texas-LTPP equation was

chosen due to this model's showing the least bias among than the other equations studied in that report.

Because the backcalculated moduli was determined by each FWD station, the prediction of the pavement temperature at the middle of the AC thickness was also carried out by each FWD stations using the MTCP software. Consequently, there is a predicted pavement temperature for each set of FWD data at each of the FWD stations in both lanes K6 and K7 that were taken in the period from 2001 to 2003. Tables 42 and 43 shows the predicted temperatures by month obtained by MTCP in both K6 and K7 lanes.

VARIATION OF THE BACKCALCULATED AC MODULUS WITH TEMPERATURE

Even though there is a large number of stations analyzed (106 stations), only the core stations are plotted in these section. Figures 50 through 64 show the backcalculated AC moduli variation due to the predicted pavement temperature in each the core stations. In these figures are presented the results from the static analysis and the dynamic (complex) modulus obtained through laboratory testing.

SELECTION OF THE PAVEMENT GROUPS.

To facilitate the better interpretation of the results of backcalculated AC modulus, it was necessary to group the FWD stations of both lanes K6 and K7. The criteria to select these pavement groups was based on two major aspects:

- the physical proximity of the FWD stations, and
- the points from the plot of the backcalculated modulus versus the predicted pavement temperature of the group should have the same trend.

Once these criteria were applied to the results, the route was divided into seven pavement groups. They are:

Pavement Group 1: From FM 511 to Coffee Port Rd.

Lane K6: FWD Stations from K6-1 to K6-15

Lane K7: FWD Stations from K7-1 to K7-15

Pavement Group 2: From Coffee Port Rd. to Dunlap St.

Lane K6: FWD Stations from K6-6 to K6-18

Lane K7: FWD Stations from K7-16 to K7-17

Pavement Group 3: From Dunlap St. to Central Ave.

Lane K6: FWD Stations from K6-19 to K6-23

Lane K7: FWD Stations from K7-18 to K7-21

Pavement Group 4: From Central Ave. to Austin Rd.

Lane K6: FWD Stations from K6-24 to K6-26

Lane K7: FWD Stations from K7-22 to K7-23

Pavement Group 5: From Austin Rd. to Fruitdale Rd.

Lane K6: FWD Stations from K6-27 to K6-36

Lane K7: FWD Stations from K7-24 to K7-33

Pavement Group 6: Fruitdale Rd. to Boca Chica Blvd.

Lane K6: FWD Stations from K6-37 to K6-41

Lane K7: FWD Stations from K7-34 to K7-37

Pavement Group 7: From Boca Chica Blvd. to Cleveland St.

Lane K6: FWD Stations from K6-42 to K6-56

Lane K7: FWD Stations from K7-38 to K7-50

SELECTION OF THE TEMPERATURE CORRECTIONS METHODS

The temperature corrections methods used in the current study are as follows:

- The Chen equation uses FWD and pavement temperature data collected from TxDOT's Mobile Load Simulator (MLS) investigations.

$$E_{Tr} = E_T (T/T_r)^{2.4462} \quad (7.1)$$

where

E_{Tr} : the modulus corrected to a reference temperature of T_r (°F)

E_T : the modulus determined from testing at a temperature of T (°F)

- The existing TX DOT equation used in the Flexible Pavement System (FPS) and load zoning analysis programs

$$E_{75} = E_T (T^{2.81}) / 185000 \quad (7.2)$$

where

E_{75} : the modulus corrected to a temperature of 75 °F

E_T : the modulus determined from testing at a temperature of T (°F)

- The Witczak and Fonseca equation (1996), which is proposed as a method for predicting the dynamic modulus in the AASHTO 2002 pavement design guide.

$$\log_{10} E = -0.261 + 0.008225p_{200} - 0.0000010(p_{200})^2 + 0.00196p_4 - 0.03157V_a - 0.415 \frac{V_{beff}}{(V_{beff} + V_a)} + \frac{[1.87 + 0.002808p_4 + 0.0000404p_{3/8} - 0.0001786(p_{3/8})^2 + 0.0164p_{3/4}]}{1 + e^{(-0.716 \log_{10} f - 0.7425 \log_{10} \eta)}} \quad (7.3)$$

where

E : asphalt mix dynamic modulus, 10^5 psi;

η : bitumen viscosity at a given temperature and degree of aging, 10^6 poises;

- f : loading frequency in Hz;
 V_a : percent of air voids by volume;
 V_{beff} : percent of effective binder content by volume;
 $p_{3/4}$: percent retained on a 3/4-inch sieve by the total aggregate weight;
 $p_{3/8}$: percent retained on a 3/8-inch sieve by the total aggregate weight;
 p_4 : percent retained on a No 4 sieve by the total aggregate weight;
 p_{200} : percent retained on a No 200 sieve by the total aggregate weight;

From the Witczak and Fonseca equation the following equation is derived for temperature correction (17):

$$\log_{10} E_R = \log_{10} E_T + \alpha \left[\frac{1}{1 + e^{-(B_R + 0.7425 \log_{10} \eta_R)}} - \frac{1}{1 + e^{-(B_T + 0.7425 \log_{10} \eta_T)}} \right] \quad (7.4)$$

where

- α : $1.87 + 0.003 p_4 + 0.00004 p_{3/8} - 0.00018 (p_{3/8})^2 + 0.0164 p_{3/4}$
 B_R : $0.716 \log_{10} f_R$
 B_T : $0.716 \log_{10} f_T$
 E_R : the AC modulus corrected for the selected reference temperature and loading frequency.
 E_T : the measured backcalculated asphalt concrete modulus;
 η_R : the binder viscosity corresponding to the reference temperature in 10^6 poises,
 η_T : binder viscosity corresponding to the test temperature in 10^6 poises,
 p_4 : the cumulative percent retained in a No. 4 sieve by the total aggregate weight;
 $p_{3/8}$: the cumulative percent retained in a No. 3/8-inch sieve by the total aggregate weight;
 $p_{3/4}$: the cumulative percent retained in a 3/4-inch sieve by the total aggregate weight;
 f_R : the reference loading frequency in Hz; and
 f_T : the test loading frequency in Hz.

In these three equations, the basic AC mixtures properties are included. The binder viscosities corresponding to test and reference temperatures are employed, to correct the measured or backcalculated moduli to specific reference temperatures.

To get the viscosity-temperature relationship for the binder used in the AC mix the equation from American Society for Testing and Material, standard ASTM-D2493 is used.

$$\log_{10} \log_{10} \eta = A + VTS \log_{10} T^{\circ}_R \quad (7.5)$$

where

- η : the binder viscosity in centipoises;
- T°_R : the temperature in degrees Rankine;
- A and VTS: the model coefficients determined from testing.

EVALUATION OF THE BINDER-VISCOSITY RELATIONSHIP

As it was said previously it was necessary to find the parameters A, VTS, and the binder viscosity to get a corrected modulus. In this study the DSR test was not done, however the values of the parameters can be obtained by regression analysis using this formula:

$$y = \delta + \frac{\alpha}{1 + e^{(\beta - \gamma x)}} \quad (7.6)$$

where

- y : $\log_{10} E$;
- δ, α : the coefficients (functions of the volumetric mixture properties);
- β : $-0.716 \log_{10} f$;
- f : $1/2\pi t$;
- γ : 0.7425; and
- x : $\log_{10} \eta$.

Equation 7.6 was developed as a function of the test temperature using equation 7.5. Employing SAS software, Eq 7.6 was solved by nonlinear regression to find the coefficients A, VTS, δ and α . Since there were no data from volumetric mixture

properties from the laboratory testing conducted for this project, a range of δ and α were obtained from the LTPP database and the results from the TTI Research Report 1863-1. These ranges were used as boundaries values in the nonlinear regression analysis to obtain the coefficients.

Tables 44 and 45 show the coefficients obtained by the nonlinear regression of each group for lanes K6 and K7. Tables 46 and 47 show the results of analysis of the variance (ANOVA) in these regression analyses. Being the p value < 0.001 , these regression equations may be acceptable. Figures 65 to 79 show a comparison between the predicted AC modulus using the Witczak and Fonseca equation (Eq. 7.6) and backcalculated AC modulus.

FIGURE 78 Comparison of the Backcalculated AC Modulus with Eq 7.6. Pavement Group 7 of the K7 Lane.

FIGURE 79 Comparison of the Backcalculated AC Modulus with Eq 7.6. C6 Core.

Since the figures of the modulus comparison between the backcalculated and the predicted by Witczak and Fonseca have been set by pavement groups and lanes, the comparison between both lanes can be seen by observing two consecutive figures.

It is important to note that the AC moduli from the K6 lane has a lesser value than the K7 lane in the same group, indicating possible damage on the K6 lane. This is supported by the field data, since the K6 lane (outside) is more frequently used by overweight trucks than K7 lane (inside).

Figure 79 belongs to the C6 core taken in the center left turn lane in the vicinity of the K6-4 FWD station. This data will be very useful later when it will be focused on the corrected modulus by temperature.

CALCULATIONS OF THE CORRECTED BACKCALCULATED AC MODULUS

Three equations of making temperature corrections were selected for this research: the Chen, the Tx DOT and the Witczak and Fonseca. The reference temperature for these corrections was determined to be 23.8 °C (75 °F). The corrected modulus by each group and by each lane were calculated using equations 7.1, 7.2, 7.4 and 7.5. The last two equations used the coefficients taken from Tables 44 and 45.

The corrected moduli were plotted by each method, with the best results coming from the Witczak and Fonseca equation. In spite of the fact that FWD data was taken in the K6 lane until December of 2002, this month was not included due to the fact that the K6 lane was being milled in that month. Thus, the FWD data analyzed for the K6 lane is only until July of 2002.

However, when the Witczak and Fonseca equations are plotted, the corrected AC modulus values from the K6 lane were rather flat or with a small decreasing slope, which show an insignificantly decreasing trend with time indicating a negligible increase in damage on this lane. This could be explained if it is considered that FWD data incorporates two effects: load and environmental conditions, since the data were taken in the wheel paths. To verify this, two additional corrections were made. First, the corrected backcalculated AC moduli from the K6 lane were corrected using the modulus temperature relationship from frequency sweep tests done in the laboratory on the core sample taken at the center left turn lane, C6. The second was using the modulus temperature relationship from K7 lane on K6 lane. The mixtures of both lanes should be the same and in the K7 lane which would have smaller load effects because it is the passing lane.

From these two additional corrections, evidence of damage was found on the K6 lane when the correction was carried out with the modulus temperature relationship from the C6 core. Figures 80 through 86 present plots of all groups of the K6 lane with the modulus temperature relationship from the C6 core. Appendix E shows the results of the temperature corrected modulus analysed in all groups stations using the Chen and TxDOT temperature corrections methods.

FIGURE 85 Evidence of Damage in the Pavement Group 6 of SH4/48.

FIGURE 86 Evidence of Damage in the Pavement Group 7 of SH4/48.

As it was said earlier, Figures 80 to 86 show the corrections done to the backcalculated AC modulus using the modulus temperature relationship from the C6 core. The corrected backcalculated AC moduli from the K6 lane show in these plots a decreasing line over time, evidence of damage to this lane. Group stations 1, 3, 5, 6 and 7 show more damage. The number of the FWD stations included in these three groups on the K6 lane are more than 50 % of segment route SH4/48.

CHAPTER VIII

DISCUSSION OF THE RESULTS

BACKCALCULATED MODULUS ERROR

Tables 12 and 13 on pages 46 through 48 reflect the accuracy of the backcalculated modulus values. Since the maximum error should be 5 %, the values obtained from these tables are less than 5 % with three exceptions at the K6-42, K6-43 and K7-38 FWD stations.

The possible reasons for these anomalies could be they are located at the beginning of the downtown area where the truck traffic is not only due to overweight loads but also due to normal traffic. It means the number of repetitions of load would be increasing more in this intersection of Boca Chica Boulevard and SH 48 with dense traffic.

BACKCALCULATED AC MODULI RELATIONSHIP BETWEEN THE STATIC ANALYSIS AND THE DYNAMIC (COMPLEX) MODULUS /E*./

The backcalculated AC results at core locations from static analysis (MODULUS) are compared with the dynamic (complex) modulus /E*./ obtained from the laboratory testing. Figures 87, and 88 show these plots and their linear correlations correspondent to a los values got from K6 and K7 lane, respectively. The Figure 89 present the combination of both K6 and K7 lane values. The linear regression found was comparable with the form:

$$/E^*/ = (1+a) E_{static} \quad (8.1)$$

where

/E*./ : dynamic (complex) modulus get from Laboratory testing,

FIGURE 89 Backcalculated AC Moduli Relationship between the Static Analysis and the Dynamic (Complex) Modulus for Both Lanes.

In these comparisons the values of K6-48 core station were separated because the values did not show the same tendency as the other cores. This deviation is explained because of K6 48 is located in the downtown area where most of the extracted core samples from the K6 lane lacked a homogeneous AC mixture as it shown in Figures 87, pictures a, b, c and d.

In the K7 lane, contrary to the K6 lane, the results from the FWD stations, K7-37 and K7 40 downtown area, fit well with the results of laboratory testing. The interpretation of this is reflected on pictures e) and f) of Figure 90 where the quality of the cores is stronger and more uniform than those in the K6 lane.

Figure 91 presents the comparison of the backcalculated AC modulus from the MODULUS program versus Dynamic (Complex) Modulus from the laboratory testing corresponding to group stations 1, 3, 4, 5 and 6 from the K6 lane. Groups 2 and 7 did not have good correlations with the closer FWD core station results. Because Group 7 is located in the downtown area, it is expected that the results from laboratory testing will not be exact.

According to Figure 92 shows that in all group stations from the K7 lane, the correlation between laboratory testing and static analysis is accurate, even in the group station 7. Once again is shown how the overweight truck traffic is impacting more on the K6 lane than K7 lane.

BACKCALCULATED AC MODULI RELATIONSHIP BETWEEN THE STATIC ANALYSIS AND THE DYNAMIC ANALYSIS.

Figures 93 and 94 plot the backcalculated AC modulus obtained from DBISD (dynamic analysis) versus those obtained from the MODULUS program (static analysis) and show their linear regression for both K6 and K7 lane. The Tables 50 and 51 present the significance of their linear regression done. Figure 95 joins both K6 and K7 lane values and present its linear regression. Table 52 show the significance of its linear regression. The linear regression found was comparable with the form:

$$\mathbf{E}_{\text{static}} = (1+b) \mathbf{E}_{\text{DBSID}} \quad (8.2)$$

where

E_{DBSID} : backcalculated AC modulus gets from dynamic analysis

E_{static} : backcalculated AC modulus gets from static analysis,

$(1+b)$: slope;

It is significant to point out that the pavement structure thicknesses selected in the static analysis (Figure 30) fit well with the dynamic analysis in both lanes K6 and K7. However, it is observed that in some stations values obtained from the MODULUS are slightly greater than the DBISD especially in the K7 lane.

- Regression Linear for K6 Lane values.

$$E_{static} = 1.047 E_{DBSID}$$

FIGURE 95 Backcalculated AC Moduli Relationship between the Static Analysis and the Dynamic Analysis for Both Lanes.

As it known backcalculated AC modulus from dynamic analysis (DBSID) is an isotropic modulus which follow this laws:

$$E_{\text{DBSID}} = \sqrt{E_{\text{VERTICAL}} * E_{\text{HORIZONTAL}}} \quad (8.3)$$

$$E_{\text{HORIZONTAL}} = \frac{E_{\text{VERTICAL}}}{c} \quad (8.4)$$

and E_{vertical} is the AC modulus gets in the laboratory testing (E^*), then it may obtained “c” value combining the Eq. 8.3 and 8.4 with 8.1 and 8.2 given this expression:

$$c = (1 + a)^2 * (1 + b)^2 \quad (8.5)$$

In this study was calculated “c” value for each lane. They are 1.3 and 1.15 for the K6 and K7 lanes, respectively. However a better result of “c” was obtained when both K6 and K7 data are analyzed together. This value is 1.26.

COMPARISON OF THE CREEP COMPLIANCE PARAMETERS OBTAINED FROM THE DYNAMIC ANALYSIS AND FROM THE LABORATORY TESTING

As it was explained in Chapter VI only the cores stations K6-1, K6-4, K6-11, K6-23 and K6-48 offered valid creep compliance parameters in the K6 lane. In the same way, the following core stations: K7-11, K7-15, K7-20, K7-31, K7-37 and K7-40, offered valid creep compliance paameters.

To process and compare “m” values between those obtained from dynamic analysis and laboratory data, it was necessary to set up a reference temperature. For convenience 23.8 °C (75 °F) was chosen. This is the same reference temperature used in the temperature corrected modulus. The “m” value from the laboratory was corrected to this reference temperature which is possible with the trendline of “m” from the laboratory temperature data as see in Figure 96 a).

The ratio $m_{\text{ref}}/m_{\text{temp}}$ for each “m” value is used to get the correction factor line. See Figure 96 b). As the correction factor line is a function of temperature, the correction factor is calculated for each ‘m’ value. The corrected value of “m” is called “ m_c ” is obtained multiplying the correction factor by the “m” values from DBSID.

FIGURE 96 Procedure to Obtain “ m_c ” .

Figures 97 and 98 show the variation of “ m_c ” with time for both the K6 and K7 lanes, respectively. The increasing values of “ m_c ” over time in the K6 lane reflects deterioration. The “m” value is related to two major problems with the asphalt pavement, fatigue cracking and permanent deformation. The increasing “m” values obtained in this analysis confirms the deterioration of the K6 lane with time. Contrary to the trends in the K6 lane, in the K7 lane “ m_c ” values show a flat line, or a very small positive slope indicating that in the K7 lane, the initial conditions of the road have undergone little change.

FIGURE 97 Variation of the “ m_c ” Values for the K6 Lane.

FIGURE 98 Variation of “ m_c ” Values for the K7 Lane.

CORRECTED BACKCALCULATED AC MODULUS WITH ENVIRONMENTAL CONDITIONS

Figures 80 through 86 present the corrected backcalculated AC modulus with environmental conditions. The fact that corrected backcalculated AC modulus from the K6 lane show a greater decreasing line overtime and lower AC moduli than the K7 lane indicate that there is evidence of damage in K6 lane.

RELATIONSHIP BETWEEN CORRECTED BACKCALCULATED AC MODULUS AND CUMULATIVE 18-kip ESALs.

A reduction in asphalt moduli with increasing amounts of 18-kip Equivalent Single Axle (ESAL) provides evidence that pavements are damaged by increasing numbers of load repetitions.

The fact that a greater amount of truck traffic travels in the K6 lane than in the K7 lane provides an opportunity to evaluate the amount of damage that is done by this traffic by plotting the observed reduction in modulus against the accumulate 18-kip Equivalent Single Axle Loads in both lanes.

To analyse the number of the ESALs in each lane it was necessary to request the current traffic data and the historical Average Daily Traffic (ADT) from Tx DOT traffic record.

TxDOT sent data corresponding to the Fiscal Year 2003, from September 2002 to August 2003, which was collected and recorded by the weigh-in-motion (WIM) stations along the SH 4/48 roadway. Table 54 shows the number of 18-kip ESALs separated into axle configuration: single, tandem, triple or quad, by monthly mean and per year (2003). In addition, the historical average daily traffic (ADT) from SH 4/48 provided by the Pharr District office was useful to calculate the traffic growth rate “g and to project backward in time to obtain the 18-kip ESALs for the past years.

Because SH 4/48 was divided on seven Pavement Groups in Chapter VII, it was necessary to select the ADT values in the same Pavement Groups to get the 18-kip ESAL in each of them. Table 55 presents the greater ADT selected values by Pavement Group.

It notes that the ADT values are the same in the Pavement Group 2, 3, 4, and 5, but different in the Pavement Group 1, 6 and 7. Equation 8.6 was used to determine the values of the Growth Rate “g” which are shown in Table 55 too.

$$g = \left(\frac{ADT_n}{ADT_o} \right)^{\frac{1}{n}} - 1 \quad (8.6)$$

where;

- g : Growth rate;
- ADT o : Average daily traffic at the start of the design period;
- ADT n : Average daily traffic at the end of the design period;
- n : Number of the years of the design period.

TABLE 54 Results of 18-kip ESALs in the Fiscal Year 2003 by Axle Configuration.

Axle configuration	By Month	By Year
Single axle	6878	82535
Tandem axle	17990	215880
Triple axle	1496	17957
Quad axle	1	13
TOTAL ESALs	26365	316385

TABLE 55 Growth Rate “g” by Pavement Group.

Pavement Group	ADT_o 1993	ADT_n 2003	Growth Factor “g”
1	14079	18974	0.0303
2,3,4,5	23511	28344	0.0189
6	28022	34356	0.0206
7	27148	29253	0.0075

Equation (8.7) was used to compute the total number of 18-kip ESAL's for each year before 2003.

$$\text{Cumulative 18-kip ESAL}_n = (\text{Total 18-kip ESAL}_o) * \left(\frac{(1+g)^n - 1}{g} \right) \quad (8.7)$$

where;

Cumulative 18-kip ESAL_n : It is the total number of the 18-kip ESAL at the year “n”;

Total 18-kip ESAL_o : It is the total number of the 18-kip ESAL at the year “o” ;

g : growth rate;

n : the number of the years between the year_n and the year_o.

The Table 56 presents the total number of 18-kip ESAL by year, from 1993 up to 2003. The year 1993 was chosen because it was during that year the SH 4/48 sections in this study were repaved.

TABLE 56 Number of the Total 18-kip ESAL by Year and Pavement Groups.

Year	Pavement Groups			
	1-1A	2 to 5	6	7

Figures 99 through 106 presents the plots of the cumulative 18-kip ESAL versus corrected backcalculated AC modulus belong to westbound direction, K6 and K7 lanes to each Pavement Group. The Figure 106 belongs to Pavement Group 1A corresponds to the first eight FWD stations to both lanes and it starts in FM 511 and ends in FM 802. These plots utilize the data from Tables 59 and 60.

In addition, a fitted curve has been added to each of the plots. Equation 8.8 was used to obtain these fitted curve. The coefficients ρ , β , E_{ASYM} , and E_0 from the Equation 8.8 were obtained by nonlinear regression. Table 61 show the results of analysis of variance (ANOVA) for each Pavement Groups.

$$E = E_{ASYM} + E_0 * \left(1 - e^{-\left(\frac{\rho}{N}\right)^\beta}\right) \quad (8.8)$$

where : E_{ASYM} , E_0 , ρ , β : Coefficients;
 E : Corrected Backcalculated AC Modulus;
 N : Cumulative 18-kip ESAL.

FIGURE 99 Plot of Cumulative 18-kip ESAL versus Corrected Backcalculated AC Modulus in the Pavement Group 1A.

FIGURE 100 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 1.

FIGURE 101 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 2.

FIGURE 102 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 3.

FIGURE 103 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 4.

FIGURE 104 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 5.

FIGURE 105 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 6.

FIGURE 106 Plot of Cumulative 18-kip ESALs versus Corrected Backcalculated AC Modulus in the Pavement Group 7.

These eight figures, Figures 99 through 106, point out how the traffic affects each lane. In each of figure the cumulative 18-kip ESAL is greater in the K6 lane than in the K7 lane, confirming the fact that the K6 lane is more heavily used by all vehicle classes. These plots clearly demonstrate that this greater cumulative 18-kip ESAL is associated with lower corrected backcalculated AC moduli in the K6 lane. It is important to note that the K7 lane carries lower cumulative 18-kip ESAL and higher corrected backcalculated AC modulus than in the K6 lane. These data confirm that more damage is produced by the greater amount of 18-kip ESALs in the K6 lane.

CHAPTER IX

CONCLUSIONS AND RECOMMENDATIONS

The impact of overweight truck traffic (OTT) on the segment route SH4/48 has been analyzed in this research by carrying out a monitoring process of FWD testing for three years on the road and breaking down their data by static and dynamic analysis. In addition, a frequency sweep test was conducted to get the Dynamic (Complex) Modulus and creep compliance parameters necessary to compare with those static and dynamic analysis and to find their correlations.

With the purpose of finding out if these OTTs produce damage to the pavement on the route SH4/48 the backcalculated AC moduli were corrected to a common temperature using the Witczak and Fonseca Equation.

These are the conclusions reached in this research:

1. There is evidence of damage on the route SH4/48 due to overweight truck traffic.
2. Combining the thickness of the flexible base layer with the salvage base layer and the treated limestone layer (Figure 32) produce the smallest errors in the backcalculated moduli in both lanes. Only the K6 42, K6 43 and K7 38 FWD stations gave errors in the order of 10% in some months.
3. A linear regression between backcalculated AC modulus from static analysis and dynamic (complex) modulus E^* from the frequency sweep lab test gave the best equation $E^* = 1.0554 E_{static}$ when the core stations from both lanes are analyzed together. The results are shown in Figure 89 and Table 50.
4. The correlation between the backcalculated AC modulus from the static analysis and the Dynamic (Complex) Modulus obtained through frequency sweep test in the laboratory are very acceptable in all FWD stations of the K7 lane (Figure 92). In the K6 lane there is a good correlations except for those values from Pavement Group 2 and the downtown area (Figure 91).

5. The AC mixture in the K6 lane in the downtown area gave the lowest backcalculated AC moduli and the dispersion of the dynamic (complex) modulus $/E^*$ (Figures B42 up to B56 and Figure 90 pictures a), b), and c) of all pavements sections in this study. This is also supported by the laboratory testing results in which from ten core samples taken in the downtown area in the K6 lane, four were disintegrated in the handling process, six were tested in the laboratory and only one core sample had acceptable values.
6. The linear regression between backcalculated AC moduli from dynamic analysis and static analysis gave the equation $E_{\text{static}} = 1.065 E_{\text{DBSID}}$, when the core stations from both lanes were analyzed together. The results are shown in the Figure 95 and Table 52.
7. The best “c” value that correlates $E_{\text{horizontal}}$ with E_{vertical} was 1.26. This is when all data from both K6 and K7 lane are combined.
8. The greater “c” value obtained in the K6 lane, 1.3, than 1.15 in the K7 lane, indicates that as damage increases, the anisotropy of the asphalt layer increase.
9. Since the corrected backcalculated AC moduli by temperature show a decreasing line on the K6 lane in mostly all Pavement Groups, this lane must have more damage than the K7 lane (Figures 98 to 104). This conclusion is supported by the m_c values from the K6 lane whose values increase with time, indicating the presence of large fatigue cracking or permanent deformation over time. Unlike the m_c values from the K7 lane which show a flat trend (Figures 97 and 98), indicating little damage.
10. The total number of the 18-kip ESAL by year (Tables 56 and 59) provides evidence of a greater use in the K6 lane than the K7 lane for all vehicle classes.
11. The greater cumulative 18-kip ESALs with lower corrected backcalculated AC modulus shown in the Figures 106 up to 113 confirm again the damage which occurred in the K6 lane due to current traffic (overweight truck).

12. The percentage by incidence of the FHWA classes 9 and 10 (overweight truck class) gave 4.21% and 0.73% percentages, respectively, (Table 57 and 58) the percentage of the ESALs for tandem axle produced by these classes is 35 % of the total 18-kip ESALs obtained from the axle distribution (Table 56).
13. Damage to asphalt flexible pavement can be detected by non-destructive FWD testing.
14. This research has proved that FWD data must be corrected for the effects of load level and environmental conditions and the resulting backcalculated modulus values are consistent with laboratory data.

RECOMMENDATIONS

Because the SH 4/48 is a segmented route which carries overweight truck traffic, it is necessary to have a homogenous hardening AC layer in all downtown areas, especially in the K6 lane FWD stations from K6 42 up to K6 56 (From Boca Chica Blvd. to Cleveland St.).

D2 BACKCALCULATION OF THE CREEP COMPLIANCE COEFFICIENTS

The program FREQSWP is used to backcalculate the creep compliance coefficients, which uses data from frequency sweep tests. The input data to this program are the storage and loss compliances at various frequencies which have been determined by the frequency sweep test data. The J_1 and J_2 are the real and imaginary part of the Creep Compliance obtained on the laboratory testing.

VITA

SONIA INES RAMOS APARICIO

PERMANENT ADDRESS

Av Morro Solar 2204 Urb Monterrico Sur Lima 33 Peru
(511) 2749512)

EDUCATION

- Texas A&M University
Master of Science in Civil Engineering, May 2003
- Universidad Nacional de Ingenieria
Bachelor of Science in Civil Engineering, December 1988

EXPERIENCE

- Texas Transportation Institute, Texas A&M System. College Station, Texas.
Research Assistant, Project: “ Characterize the Effects of Permitted Overweight Loads on SH 4/48 in the Port of Brownsville.” Aug 2000- Aug 2003.
- Ministry of the Presidency. Peru Government.
Inspector and Coordinator Engineer of civil work related to highways. Jan 1998- April 1999.
- Peru Government and Inter-American Development Bank.
Inspector and Coordinator Engineer of civil works from Ministry of Education especially the elementary and high schools built in the coast and mountain of Peru. Jan 1997- Dec 1997.
- Fletcher Challenge Group, Firth Industries Peru, Premix Concrete
Aggregate Plant Supervisor Engineer with training in New Zealand in aggregate plants operations and quality control of aggregate production. 1996.
- Universidad Nacional de Ingenieria.
Assistant Professor, Department of Civil Engineering. Jan 1991- Dec 1995.
