In ultra-peripheral relativistic heavy-ion collisions, a photon from the electromagnetic field of one nucleus can fluctuate to a quark-antiquark pair and scatter from the other nucleus, emerging as a ρ^0. The ρ^0 production occurs in two well-separated (median impact parameters of 20 and 40

fermi for the cases considered here) nuclei, so the system forms a 2-source interferometer. At low transverse momenta, the two amplitudes interfere destructively, suppressing ρ^0 production. Since the ρ^0 decays before the production amplitudes from the two sources can overlap, the two-pion system can only be described with an entangled non-local wave function, and is thus an example of the Einstein-Podolsky-Rosen paradox. We observe this suppression in 200 GeV per nucleon-pair gold-gold collisions. The interference is $87\% \pm 5\%$(stat.)$\pm 8\%$ (syst.) of the expected level. This translates into a limit on decoherence due to wave function collapse or other factors, of 23% at the 90% confidence level.

Relativistic heavy ions carry strong electromagnetic fields which can be treated as sources of quasi-real virtual photons. When two ions collide, a large variety of two-photon and photonuclear interactions can occur [1]. In coherent vector meson photoproduction, a photon from the field of one nucleus fluctuates into a virtual quark-antiquark pair which scatters elastically from the other nucleus, emerging as a real vector meson. ρ^0 photoproduction has a large cross section, 8-10% of the hadronic cross section for gold-gold collisions at a center-of-mass energy of 200 GeV per nucleon-pair [2, 3, 4]. Photoproduction can occur at large impact parameters, b. For ρ^0 photoproduction the median b is about 46 fm [5].

The $(q\overline{q})N$ scattering that produces ρ^0 occurs via the short-ranged strong force; the ρ^0 is produced within one of the two ions. The ρ^0 source consists of two well-separated nuclei. There are two possibilities: either nucleus 1 emits a photon which scatters off nucleus 2, or vice versa. These two possibilities are indistinguishable, and are related by a parity transformation. Vector mesons have negative parity, so the two amplitudes combine with opposite signs. The nuclear separation can be accounted for with a transverse momentum (p_T) dependent phase factor. The cross section is [6]

$$\sigma(p_T, b, y) = \left| A(p_T, b, y) - A(p_T, b, -y) \exp\left(i\vec{p}_T \cdot \vec{b}\right) \right|^2,$$
(1)

where $A(p_T, b, y)$ and $A(p_T, b, -y)$ are the amplitudes at rapidity y for ρ^0 production from the two photon directions. We take $\hbar = c = 1$ here. At mid-rapidity the amplitudes for the two directions are equal, and

$$\sigma(p_T, b, 0) = 2|A(p_T, b, 0)|^2 \left[1 - \cos\left(\vec{p}_T \cdot \vec{b}\right) \right]. \quad (2)$$

The system acts as a 2-slit interferometer, with slit separation $b = |\vec{b}|$. The cross-sections at different $\vec{b}$ are added, and the p_T spectrum is obtained by integrating Eq. (1) over $\vec{b}$. ρ^0 production is suppressed for $p_T \lesssim 1/\langle b \rangle$, where $\langle b \rangle$ is the mean impact parameter.

The ρ^0 rapidity y and mass m_V and the photon energy k_i are related by $k_{1,2} = (m_V/2) \exp(\pm y)$ where the subscript refers to the two directions. Away from $y = 0$, $k_1 \neq k_2$, so $A(p_T, b, y) \neq A(p_T, b, -y)$, and the interference in Eq. (1) is less than maximal.

There are two theoretical calculations of this interference. Klein and Nystrand [6] calculated the interference using a detailed nuclear form factor, averaging the photon flux over the nucleus. Hencken, Baur and Trautmann used a more detailed model of the photon profile and a Gaussian form factor for the nucleus [7]. This work only considered production at mid-rapidity ($y = 0$), and so cannot be directly compared with the data presented here. At $y = 0$, the two calculations agree quite well.

If the ρ^0 production phase depends on the photon energy, this would introduce a $y-$dependent phase shift into Eq. (1). This is not expected in the soft-Pomeron model [8], and we assume that this phase difference is negligible.

The produced ρ^0s decay almost immediately at two well-separated points, so any interference must develop after the decay, and involve the $\pi^+\pi^-$ final state. Since the pions go in different directions, this requires an entangled $\pi^+\pi^-$ wave function which cannot be factorized into separate π^+ and π^- wave functions; this is an example of the Einstein-Podolsky-Rosen paradox [9, 10]. A measurement of the two-source interference is sensitive to any loss of quantum mechanical coherence, be it due to interactions with the environment [11] or as a characteristic of the ρ^0 decay.

Interference is also expected when the ρ^0 photoproduction is accompanied by mutual Coulomb excitation of the two nuclei. This reaction proceeds primarily via three independent single-photon subreactions (one to excite each nucleus, and one to produce the ρ^0) [5]. At a given b, the cross-section for the subreactions factorizes; the probability for an n-photon reaction is $P_n(b) = \prod_{i=1}^{n} P_i(b)$ [12], where $P_i(b)$ is the probability for subreaction i. Therefore, these multi-photon reactions have much smaller $\langle b \rangle$ and the effect of interference extends to higher p_T [5]. Because of the different $\langle b \rangle$, multi-photon interactions are important for studying this interference. The Klein-Nystrand model uses measured photonuclear cross-sections for the mutual Coulomb excitation [13], while Hencken, Baur and Trautmann used the Giant Dipole Resonance, plus a correction. For e^+e^- production accompanied by nuclear breakup, using the measured mutual breakup cross-sections rather than the Hencken Baur and Trautmann approach leads to a 20% larger cross-section [14]; a similar difference may apply for ρ^0 photoproduction.

In this letter we measure two-source interference in 200 GeV per nucleon-pair gold-gold collisions by studying the transverse momentum (p_T) spectrum of photoproduced ρ^0s. These data were taken with the STAR
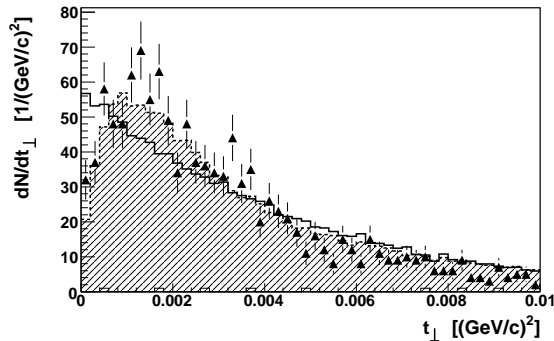

FIG. 2: Raw (uncorrected) ρ^0 $t_\perp$-spectrum in the range $0.0 < |y| < 0.5$ for the MB data. The points are data, with statistical errors. The dashed (filled) histogram is a simulation with an interference term ("Int"), while the solid histogram is a simulation without interference ("NoInt"). The handful of events histogrammed at the bottom of the plot are the wrong-sign $(\pi^+\pi^+ + \pi^-\pi^-)$ events, used to estimate the combinatorial background.

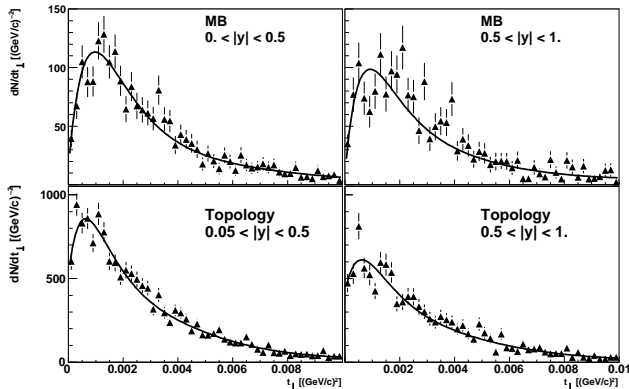

FIG. 3: Efficiency corrected $t_\perp$ spectrum for ρ^0 from (top) minium bias and (bottom) topology data, for mid-rapidity (left) and larger rapidity (right) samples. The points are the data, while the solid lines are the results of fits to Eq. (3).

is the ratio of the simulated $t_\perp$-spectra with and without interference. For $t_\perp \gg 0.01\text{GeV}^2$, $R(t_\perp) \to 1$, but for $t_\perp \leq 0.01$ GeV^2, $R(t_\perp) \neq 1$. A is the overall (arbitrary) normalization and c gives the degree of spectral modification; $c = 0$ corresponds to no interference, while $c = 1$ is the predicted Klein-Nystrand interference. Table 1 gives the fit results.

$R(t_\perp)$ was determined using a simulation that includes the detector response, and then fit to two analytic functions: $R(t_\perp) = \Sigma_{i=0}^n a_i/(t_\perp + 0.012\text{GeV}^2)^i$ and $R(t_\perp) = \Sigma_{i=0}^n a_i t_\perp^i$. Our results use the first polynomial with $n = 5$; the second polynomial and different values of n were used to estimate the fitting uncertainties.

The weighted average of the four c values is $c = 0.84 \pm 0.05$. The k values for the MB and topology datasets differ by 15%. This may be due to the differ-

Dataset	A	k (GeV^{-2})	c	$\chi^2/$ DOF
MB, $|y| < 0.5$	$6,471 \pm 301$	299 ± 12	0.92 ± 0.07	45/47
MB, $0.5 < |y| < 1.0$	$5,605 \pm 330$	303 ± 15	0.92 ± 0.09	76/47
T, $0.05 < |y| < 0.5$	$11,070 \pm 311$	350 ± 8	0.73 ± 0.10	53/47
T, $0.5 < |y| < 1.0$	$12,060 \pm 471$	333 ± 11	0.77 ± 0.18	64/47

TABLE I: The results of fitting Eq. 3 to the four data sets. Here, T is for topology. The χ^2/DOF are discussed in the text.

ent b distributions. The photon flux scales as $1/b^2$, so the photon flux on the 'near' side of the nucleus is larger than on the 'far' side. As b decreases, ρ^0 production is increasingly concentrated on the near side, and the apparent production volume drops, reducing k. A calculation with different assumptions may predict a different electric field variation which leads to a smaller difference in k.

Two of the fits have χ^2/DOF significantly larger than 1. The χ^2 did not decrease with different fit functions for $R(t)$, variations of the nuclear radius in the interference calculations, background level, or modifications to the detector simulation. When the $\chi^2/DOF > 1$, we scale up the fit errors on c by $\sqrt{\chi^2/DOF}$; this excess error may have theoretical and/or experimental origin. With the scaled errors, the weighted average is $c = 0.86 \pm 0.05$.

Systematic errors come from instrumental effects, background, fitting, and theoretical issues. The major instrumental effects were due to the topology trigger; we apply a 10% systematic error to the topology data to account for this.

This analysis is sensitive to any ρ^0 p_T-dependent efficiency variation. The decay pions have a typical p_T of about 300 MeV/c, where the detection efficiency is high and almost p_T-independent [15]. However, the ρ^0 p_T resolution, about 7.5 MeV/c, smears the $t_\perp$ spectrum in the two lowest $t_\perp$ bins. To study detector effects, we fit the raw (uncorrected) $t_\perp$ spectrum with the raw Monte Carlo output; this reduced c by 18% [21], mostly due to the p_T smearing. We assume conservatively that the detector simulation is only 80% effective, and assign a 4% systematic error on c to account for non-trigger detector effects.

Backgrounds were estimated by including like-sign pairs $(\pi^+\pi^+ + \pi^-\pi^-)$ in the fits. c changed by less than 0.5%. We assign a 1% systematic error due to backgrounds.

The uncertainty due to fitting was evaluated by comparing results using the two different polynomial forms of $R(t)$ for both $n = 4$ and $n = 5$; c varied by an average of 1%. The effect of an imperfect form factor model was studied by varying the nuclear radius in the simulations. A $\pm 20\%$ change in nuclear radius changed c by 3%. We assign a 4% systematic error due to the fitting procedure.

The theoretical uncertainties are difficult to evaluate. Our simulation follows Refs. [5, 6] in detail, but those calculations themselves contain uncertainties. The two theoretical models agree well for exclusive ρ^0 production. For ρ^0 production accompanied by mutual Coulomb excitation, there is some disagreement, but the Klein-Nystrand model has a more detailed excitation calculation, and so may be more accurate. We assign a 5% systematic error due to theoretical issues.

Combining these systematic errors in quadrature results in an 8% (13%) systematic error for the MB (topology) data. Adding the four results in quadrature, including the systematic errors, leads to an interference that is $87 \pm 5(\text{stat.}) \pm 8\%(\text{syst.})$ of the expected level.

Because ρ^0s decay so rapidly, $\gamma\beta c\tau \ll \langle b \rangle$, the ρ^0 decay points are well separated in space-time, and the two amplitudes cannot overlap and interfere until after the decay occurs. The interference must involve the $\pi\pi$ final states [9]. This interference is only possible if the post-decay $\pi\pi$ wave functions retain amplitudes for all possible ρ^0 decays, at least until the wave functions from the two ion sources overlap. The $\pi^+\pi^-$ wave function is not factorizable and is thus an example of the Einstein-Podolsky-Rosen paradox [10]. Unlike previous tests of non-locality, the interference involves continuous variables, momentum and position [9].

In conclusion, we have measured the interference between ρ^0 production at two sources (the two nuclei) by observing the $\pi^+\pi^-$ decay products. We observe the interference at $87 \pm 5(\text{stat.}) \pm 8$ (syst.)% of the expected level. This shows that the final state wave function retains amplitudes for all possible decays, long after the decay occurs. The maximum decoherence (loss of interference) is less than 23% at the 90% confidence level.
