First run II measurement of the W boson  
mass at the Fermilab Tevatron

T. Aaltonen, A. Abulencia, J. Adelman, T. Akimoto, M. G. Albrow, B. A. Gonzalez, S. Amerio, D. Amidei, A. Anastasov, A. Annovi, J. Antos, G. Apollinari, A. Apresyan, T. Arisawa, A. Artikov, W. Ashmanskas, A. Attal, A. Aurisano, F. Azfar, P. Azzi-Bacchetta, P. Azzurri, N. Bacchetta, W. Badgett, A. Barbaro-Galtieri, V. E. Barnes, B. A. Barnett, S. Baroiant, V. Bartsch, G. Bauer, P. H. Beauchemin, F. Bedeschi, P. Bednar, S. Behari, G. Bellettini, J. Bellinger, A. Belloni, D. Benjamin, A. Beretvas, J. Beringer, T. Berry, A. Bhatti, M. Binkley, D. Bisello, I. Bizjak, R. E. Blair, C. Blocker, B. Blumenfeld, A. Bocci, A. Bodek, V. Boisvert, G. Bolla, A. Bolshov, D. Bortoletto, J. Boudreau, A. Boveia, B. Brau, L. Brigliadori, C. Bromberg, E. Brubaker, J. Budagov, H. S. Budd, S. Budd, K. Burkett, G. Busetto, P. Bussey, A. Buzatu, K. L. Byrum, S. Cabrera, M. Campanelli, M. Campbell, F. Canelli, A. Canepa, D. Carlsmith, R. Carosi, S. Carrillo, S. Carron, B. Casal, M. Casarsa, A. Castro, P. Catastini, D. Cauz, M. Cavalli-Sforza, A. Cerri, L. Cerrito, S. H. Chang, Y. C. Chen, M. Chertok, G. Chiarelli, G. Chlachidze, F. Chlebana, K. Cho, D. Chokheli, J. P. Chou, G. Choudalakis, S. H. Chuang, K. Chung, W. H. Chung, Y. S. Chung, C. I. Ciobanu, M. A. Ciocci, A. Clark, D. Clark, G. Compostella, M. E. Convery, J. Conway, B. Cooper, K. Copic, M. Cordelli, G. Cortiana, F. Crescioli, C. C. Almenar, J. Cuevas, R. Culbertson, J. C. Cully, D. Dagenhart, M. Datta, T. Davies, P. de Barbaro, S. De Cecco, A. Deisher, G. De Lentdecker, G. De Lorenzo, M. Dell'Orso, L. Demortier, J. Deng, M. Deninno, D. De Pedis, P. F. Derwent, G. P. Di Giovanni, C. Dionisi, B. Di Ruzza, J. R. Dittmann, M. D'Onofrio, S. Donati, P. Dong, J. Donini, T. Dorigo, S. Dube, J. Efron, R. Erbacher, D. Errede, S. Errede, R. Eusebi, H. C. Fang, S. Farrington, W. T. Fedorko, R. G. Feild, M. Feindt, J. P. Fernandez, C. Ferrazza, R. Field, G. Flanagan, R. Forrest, S. Forrester, M. Franklin, J. C. Freeman, I. Furic, M. Gallinaro, J. Galyardt, F. Garberson, J. E. Garcia, A. F. Garfinkel, H. Gerberich, D. Gerdes, S. Giagu, P. Giannetti, K. Gibson, J. L. Gimmell, C. Ginsburg, N. Giokaris, M. Giordani, P. Giromini, M. Giunta, V. Glagolev, D. Glenzinski, M. Gold, N. Goldschmidt, J. Goldstein, A. Golossanov, G. Gomez, G. Gomez-Ceballos, M. Goncharov, O. Gonzalez, I. Gorelov, A. T. Goshaw, K. Goulios, A. Gresele, S. Grinstein, C. Grosso-Pilcher, R. C. Group, U.

Grundler, J. G. da Costa, Z. Gunay-Unalan, C. Haber, K. Hahn, S. R. Hahn, E. Halkiadakis, A. Hamilton, B. Y. Han, J. Y. Han, R. Handler, F. Happacher, K. Hara, D. Hare, M. Hare, S. Harper, R. F. Harr, R. M. Harris, M. Hartz, K. Hatakeyama, J. Hauser, C. Hays, M. Heck, A. Heijboer, B. Heinemann, J. Heinrich, C. Henderson, M. Herndon, J. Heuser, S. Hewamanage, D. Hidas, C. S. Hill, D. Hirschbuehl, A. Hocker, S. Hou, M. Houlden, S. C. Hsu, B. T. Huffman, R. E. Hughes, U. Husemann, J. Huston, J. Incandela, G. Introzzi, M. Iori, A. Ivanov, B. Iyutin, E. James, B. Jayatilaka, D. Jeans, E. J. Jeon, S. Jindariani, W. Johnson, M. Jones, K. K. Joo, S. Y. Jun, J. E. Jung, T. R. Junk, T. Kamon, D. Kar, P. E. Karchin, Y. Kato, R. Kephart, U. Kerzel, V. Khotilovich, B. Kilminster, D. H. Kim, H. S. Kim, J. E. Kim, M. J. Kim, S. B. Kim, S. H. Kim, Y. K. Kim, N. Kimura, L. Kirsch, S. Klimentenko, M. Klute, B. Knuteson, B. R. Ko, S. A. Koay, K. Kondo, D. J. Kong, J. Konigsberg, A. Korytov, A. V. Kotwal, J. Kraus, M. Kreps, J. Kroll, N. Krumnack, M. Kruse, V. Krutelyov, T. Kubo, S. E. Kuhlmann, T. Kuhr, N. P. Kulkarni, Y. Kusakabe, S. Kwang, A. T. Laasanen, S. We describe a measurement of the  $W$  boson mass  $m_W$  using 200 pb<sup>-1</sup> of  $\sqrt{s} = 1.96$  TeV  $p\bar{p}$  collision data taken with the CDF II detector. With a sample of 63 964  $W \rightarrow e\nu$  candidates and 51 128  $W \rightarrow \mu\nu$  candidates, we measure  $m_W = [80.413 \pm 0.034(\text{stat}) \pm 0.034(\text{sys}) = 80.413 \pm 0.048]$  GeV/ $c^2$ . This is the single most precise  $m_W$  measurement to date. When combined with other measured electroweak parameters, this result further constrains the properties of new unobserved particles coupling to  $W$  and  $Z$  bosons.

## I. INTRODUCTION

The discovery of the  $W$  and  $Z$  bosons in 1983 [1] confirmed a central prediction of the unified model of electromagnetic and weak interactions [2]. Initial  $W$  and  $Z$  boson mass measurements verified the tree-level predictions of the theory, with subsequent measurements probing the predicted  $\mathcal{O}(3 \text{ GeV}/c^2)$  [3,4] radiative corrections to the masses. The current knowledge of these masses and other electroweak parameters constrains additional radiative corrections from unobserved particles such as the Higgs boson or supersymmetric particles. These constraints are however limited by the precision of the measured  $W$  boson mass  $m_W$ , making improved measurements of  $m_W$  a high priority in probing the masses and electroweak couplings of new hypothetical particles. We describe in this article the single most precise  $m_W$  measurement [5] to date.

The  $W$  boson mass can be written in terms of other precisely measured parameters in the ‘‘on-shell’’ scheme as [4]

$$m_W^2 = \frac{\hbar^3}{c} \frac{\pi\alpha_{\text{EM}}}{\sqrt{2}G_F(1 - m_W^2/m_Z^2)(1 - \Delta r)}, \quad (1)$$

where  $\alpha_{\text{EM}}$  is the electromagnetic coupling at the renormalization energy scale  $Q = m_Z c^2$ ,  $G_F$  is the Fermi weak coupling extracted from the muon lifetime,  $m_Z$  is the  $Z$  boson mass, and  $\Delta r$  includes all radiative corrections. Fermionic loop corrections increase the  $W$  boson mass by terms proportional to  $\ln(m_Z/m_f)$  for  $m_f \ll m_Z$  [4], while the loop containing top and bottom quarks (Fig. 1) increases  $m_W$  according to [6]

FIG. 1. The one-loop contribution to the  $W$  boson mass from top and bottom quarks.

$$\Delta r_{tb} = \frac{c}{\hbar^3} \frac{-3G_F m_W^2}{8\sqrt{2}\pi^2(m_Z^2 - m_W^2)} \left[ m_t^2 + m_b^2 - \frac{2m_t^2 m_b^2}{m_t^2 - m_b^2} \ln(m_t^2/m_b^2) \right], \quad (2)$$

where the second and third terms can be neglected since  $m_t \gg m_b$ . Higgs loops (Fig. 2) decrease  $m_W$  with a contribution proportional to the logarithm of the Higgs mass ( $m_H$ ). Contributions from possible supersymmetric particles are dominated by squark loops (Fig. 3) and tend to increase  $m_W$ . Generally, the lighter the squark masses and the larger the squark weak doublet mass splitting, the larger the contribution to  $m_W$ . The total radiative correction from supersymmetric particles can be as large as several hundred MeV/ $c^2$  [7].

Table I [8] shows the change in  $m_W$  for  $+1\sigma$  changes in the measured standard model input parameters and the effect of doubling  $m_H$  from 100 GeV/ $c^2$  to 200 GeV/ $c^2$ . In addition to the listed parameters, a variation of  $\pm 1.7$  MeV/ $c^2$  on the predicted  $m_W$  arises from two-loop sensitivity to  $\alpha_s$ , e.g. via gluon exchange in the quark loop in Fig. 1. Theoretical corrections beyond second order, which have yet to be calculated, are estimated to affect the  $m_W$  prediction by  $\pm 4$  MeV/ $c^2$  [8].

The uncertainties on the  $m_W$  prediction can be compared to the 29 MeV/ $c^2$  uncertainty on the world average from

FIG. 2. Higgs one-loop contributions to the  $W$  boson mass.

FIG. 3. One-loop squark contributions to the  $W$  boson mass.

TABLE I. The effect on  $m_W$  of  $+1\sigma$  increases of the input parameters dominating the uncertainty on the  $m_W$  prediction. Since the Higgs boson has not been observed, we show the effect of doubling the Higgs boson mass from  $100 \text{ GeV}/c^2$  to  $200 \text{ GeV}/c^2$  [8].

Parameter shift	$m_W$ Shift ( $\text{MeV}/c^2$ )
$\Delta \ln m_H = +0.693$	-41.3
$\Delta m_t = +1.8 \text{ GeV}/c^2$ [9]	11.0
$\Delta \alpha_{\text{EM}}(Q = m_Z c^2) = +0.00035$ [10]	-6.2
$\Delta m_Z = +2.1 \text{ MeV}/c^2$ [11]	2.6

TABLE II. Direct measurements of the  $W$  boson mass, the preliminary combined LEP average, the combined Tevatron Run I average, and the preliminary world average.

Experiment	$m_W$ ( $\text{GeV}/c^2$ )
ALEPH [12]	$80.440 \pm 0.051$
OPAL [13]	$80.416 \pm 0.053$
L3 [14]	$80.270 \pm 0.055$
DELPHI [15]	$80.336 \pm 0.067$
CDF Run I [16]	$80.433 \pm 0.079$
D0 Run I [17,18]	$80.483 \pm 0.084$
LEP average [19]	$80.376 \pm 0.033$
Tevatron Run I average [20]	$80.456 \pm 0.059$
World average	$80.392 \pm 0.029$

direct  $m_W$  measurements (Table II), which include results from four experiments, ALEPH [12], DELPHI [15], L3 [14], and OPAL [13], studying  $\sqrt{s} = 161 - 209 \text{ GeV}$   $e^+e^-$  collisions at the LEP, and from two experiments, CDF [16] and D0 [17,18], studying  $\sqrt{s} = 1.8 \text{ TeV}$   $p\bar{p}$  collisions in Run I of the Fermilab Tevatron. The current experimental  $m_W$  uncertainty is a factor of 2 larger than the uncertainty from radiative corrections, excluding the Higgs contribution (Table I). The Higgs mass constraint extracted from the  $W$  boson mass is thus limited by the direct  $m_W$  measurement. The precise  $m_W$  measurement described in this article has a significant impact on the world-average  $m_W$ .

## II. OVERVIEW

A measurement of  $m_W$  at a  $p\bar{p}$  collider [21] is complementary to that at an  $e^+e^-$  collider. Individual  $u$  ( $d$ ) quarks inside the proton can interact with  $\bar{d}$  ( $\bar{u}$ ) quarks inside the antiproton (or vice versa), allowing single  $W^+$  ( $W^-$ ) boson production, which is not possible at an  $e^+e^-$  collider. In addition,  $p\bar{p}$  colliders have higher center-of-mass energies and  $W$  boson production cross sections. This provides high statistics for the leptonic decays of the  $W$  boson, which are studied exclusively because of the overwhelming hadronic-jet background in the quark decay channels. The leptonic decays of singly produced  $Z$  bosons provide

important control samples, since both leptons from  $Z$  boson decay are well measured. The production and decay uncertainties on the measurement of  $m_W$  from  $p\bar{p}$  and  $e^+e^-$  collider data are almost completely independent [22].

We present in this section an overview of  $W$  and  $Z$  boson production at the Tevatron, a description of the coordinate definitions and symbol conventions used for this measurement, and a broad discussion of our  $m_W$  measurement strategy.

### A. $W$ and $Z$ boson production and decay

$W$  and  $Z$  bosons are produced in  $\sqrt{s} = 1.96 \text{ TeV}$   $p\bar{p}$  collisions primarily through  $s$ -channel annihilation of valence  $u$  and/or  $d$  quarks (Fig. 4), with a smaller  $\mathcal{O}(20\%)$  contribution from sea quarks. The interacting quark has a fraction  $x_p$  of the proton's total momentum, and similarly the antiquark has a fraction  $x_{\bar{p}}$  of the antiproton's momentum. The resulting  $W$  or  $Z$  boson is produced at a center-of-mass energy  $\sqrt{\hat{s}} \equiv Q = mc^2$ , where  $m$  is the boson mass. The rate of production can be predicted from two components: (1) the momentum fraction distributions of the quarks,  $f_q(x, Q^2)$ , which are determined from fits to world data [23,24]; and (2) a perturbative calculation of the  $q\bar{q}' \rightarrow W$  or  $Z$  boson process [25].

$W$  and  $Z$  bosons can decay to lepton or quark pairs. Decays to quark pairs are not observable given the large direct  $q\bar{q}'$  background, and decays to  $\tau \rightarrow \nu_\tau + \text{hadrons}$  are not as precisely measured as boson decays to electrons or muons. For these reasons we restrict ourselves to the direct electronic and muonic decays ( $W \rightarrow e\nu$ ,  $W \rightarrow \mu\nu$ ,  $Z \rightarrow ee$ , and  $Z \rightarrow \mu\mu$ ), with the corresponding decays to  $\tau \rightarrow \text{leptons}$  considered as backgrounds to these processes (Sec. VIII). The branching ratio for each leptonic decay  $W \rightarrow l\nu$  ( $Z \rightarrow ll$ ) is  $\approx 11\%$  (3.3%), and the measured cross section times branching ratio is  $(2749 \pm 174) \text{ pb}$  [ $(254.9 \pm 16.2) \text{ pb}$ ] [26].

FIG. 4. Leading-order annihilation of a quark and antiquark inside the proton and antiproton, respectively, producing a  $W^+$  or  $Z^0$  boson. The quark (antiquark) has energy  $x_p E_p$  ( $x_{\bar{p}} E_{\bar{p}}$ ), where  $E_p$  ( $E_{\bar{p}}$ ) represents the total proton (antiproton) energy. The production occurs at a partonic center-of-mass energy  $Q$ . The  $u\bar{u} \rightarrow Z^0$  and  $d\bar{d} \rightarrow W^-$  processes are similar.

## B. Conventions

We use both Cartesian and cylindrical coordinate systems, in which  $+z$  points in the direction of the proton beam (east) and the origin is at the center of the detector. In the right-handed Cartesian coordinate system,  $+x$  points north (outward from the ring) and  $+y$  points upward; in the cylindrical system,  $\phi$  is the azimuthal angle and  $r$  is the radius from the center of the detector in the  $xy$  plane. The rapidity  $y = -\frac{1}{2} \ln[(E - p_z c)/(E + p_z c)]$  is additive under Lorentz boosts along the  $z$  axis. For massless particles, this quantity is equal to the pseudorapidity  $\eta = -\ln[\tan(\theta/2)]$ , where  $\theta$  is the polar angle with respect to the  $z$  axis. All angles are quoted in radians unless otherwise indicated.

Because the interacting quarks' longitudinal momenta  $p_z$  are not known for each event, we generally work with momenta transverse to the beam line. The interacting protons and antiprotons have no net transverse momentum. Electron energy (muon momentum) measured using the calorimeter (tracker) is denoted as  $E(\vec{p})$ , and the corresponding transverse momenta  $\vec{p}_T$  are derived using the measured track direction and neglecting particle masses. The event calorimetric  $\vec{p}_T$ , excluding the lepton(s), is calculated assuming massless particles using calorimeter tower energies (Sec. III A 2) and the charged lepton production vertex, and provides a measurement of the recoil momentum vector  $\vec{u}_T$ . The component of recoil projected along the charged lepton direction is denoted  $u_{\parallel}$  and the orthogonal component is  $u_{\perp}$  (Fig. 5). The transverse momentum imbalance in a  $W$  boson event is a measure of the neutrino transverse momentum  $\vec{p}_T^{\nu}$  and is given by  $\vec{p}_T^{\nu} = -(\vec{p}_T^l + \vec{u}_T)$ , where  $\vec{p}_T^l$  is the measured charged lepton transverse momentum.

When an electromagnetic charge is not indicated, both charges are considered. We use units where  $\hbar = c \equiv 1$  for the remainder of this paper.

## C. Measurement strategy

The measurement of the final state from  $W \rightarrow l\nu$  decays involves a measurement of  $\vec{p}_T^l$  and the total recoil  $\vec{u}_T$ . The neutrino escapes detection and the unknown initial partonic  $p_z$  precludes the use of  $p_z$  conservation in the mea-

FIG. 5. A  $W$  boson event, with the recoil hadron momentum ( $\vec{u}_T$ ) separated into axes parallel ( $u_{\parallel}$ ) and perpendicular ( $u_{\perp}$ ) to the charged lepton.

surement. The boson invariant mass is thus not reconstructible; rather, the two-dimensional “transverse mass”  $m_T$  is used in the  $m_W$  fit:

$$m_T = \sqrt{2p_T^l p_T (1 - \cos\Delta\phi)}, \quad (3)$$

where  $\Delta\phi$  is the angle in the transverse plane between the leptons, whose masses are negligible. The fit to the  $m_T$  distribution provides the statistically most precise measurement of  $m_W$ .

The charged lepton, which can be measured precisely, carries most of the observable mass information in the event. We calibrate the muon momentum using high-statistics samples of the meson decays  $J/\psi \rightarrow \mu\mu$  and  $Y \rightarrow \mu\mu$ , which are fully reconstructible and have well known masses. This results in a precise track momentum calibration, which we transfer to the calorimeter with a fit to the ratio of calorimeter energy to track momentum ( $E/p$ ) of electrons from  $W$  boson decays. The accuracy of these calibrations is demonstrated by applying them to measurements of the  $Z$  boson mass in the muon and electron decay channels. We then incorporate the known  $Z$  boson mass as an additional calibration constraint.

The other directly measurable quantity needed for the calculation of  $m_T$  is the recoil transverse momentum  $\vec{u}_T$ . Since the  $W$  and  $Z$  bosons are produced at a similar  $Q^2$ , they have similar recoil distributions. We use the leptons from the  $Z$  boson decay to measure the  $p_T$  of the  $Z$  boson. We then calibrate our model of  $\vec{u}_T$  by measuring the balance between the recoil and  $Z$  boson  $\vec{p}_T$ . The  $Z$  boson statistics are sufficient to perform a recoil calibration to 1% accuracy, which leads to a systematic uncertainty commensurate with other uncertainties on  $m_W$ .

To accurately model the shape of the  $m_T$  distribution, we use a fast Monte Carlo simulation of the  $p\bar{p} \rightarrow W \rightarrow l\nu$  process including the recoil and the detector response. The custom fast simulation allows flexibility in parametrizing the detector response and in separating the effects of the detector model components. We use a binned likelihood to fit the measured  $m_T$  distributions to templates (Sec. II D) generated from the fast simulation, with  $m_W$  as the free parameter. All  $m_W$  and lepton energy scale fits are performed with this procedure.

Though less statistically precise, the  $p_T^l$  and  $p_T^{\nu}$  distributions provide additional information on the  $W$  boson mass and are used as important tests of consistency. We separately fit these distributions for  $m_W$  and combine all fits in our final result.

During the measurement process, all  $W$  boson mass fits were offset by a single unknown random number chosen from a flat distribution in the range  $[-100, 100]$  MeV. The fit result was thus blinded to the authors until the analysis was complete [27]. The final measured  $m_W$  and its uncertainty have not changed since the random offset was removed from the fit results.

We give a brief overview of the template likelihood fitting procedure in Sec. IID. Section III describes the detector and the fast detector simulation used in the analysis. The  $W$  boson measurement samples are defined in Sec. IV. We describe the precision measurements of muons and electrons in Secs. V and VI, respectively. These sections include event selection, calibration, and resolution studies from the dilepton and  $W$  boson data samples. Measurement of the recoil response and resolution is presented in Sec. VII. The backgrounds to the  $W$  boson sample are discussed in Sec. VIII. Theoretical aspects of  $W$  and  $Z$  boson production and decay, including constraints from the current data sample, are described in Sec. IX. We present the  $W$  boson mass fits and cross-checks in Sec. X. Finally, in Sec. XI we show the result of combining our measurement with previous measurements, and the corresponding implications on the predicted standard model Higgs boson mass.

#### D. Template likelihood fits

All the fits involving mass measurements and the energy scale (Secs. V, VI, and X) are performed with a template binned likelihood fitting procedure. A given distribution to be fit is generated as a discrete function of the fit parameter, using the fast simulation. These simulated distributions are referred to as “templates.” For each value of the fit parameter, the simulated distribution is compared to the data distribution and the logarithm of a binned likelihood is calculated. The binned likelihood is the Poisson probability for each bin to contain the  $n_i$  observed data events given  $m_i$  expected events, multiplied over the  $N$  bins in the fit range:

$$\mathcal{L} = \prod_{i=1}^N \frac{e^{-m_i} n_i^{m_i}}{n_i!}. \quad (4)$$

We calculate the logarithm of the likelihood using the approximation  $\ln n! \approx (n + 1/2) \ln(n + 1) - n$ :

$$\ln \mathcal{L} \approx \sum_{i=1}^N [n_i \ln m_i - m_i - (n_i + 1/2) \ln(n_i + 1) + n_i]. \quad (5)$$

The best-fit value of the parameter maximizes the likelihood (or equivalently minimizes  $-\ln \mathcal{L}$ ), and the  $\pm 1\sigma$  values are those that increase  $-\ln \mathcal{L}$  by  $1/2$ . The approximation for  $\ln n!$  only affects the value of the likelihood at the minimum and not the fit results. The procedure is validated by fitting simulated data (“pseudoexperiments”) and no bias is found. We symmetrize the uncertainty on the fit parameter by taking half the difference between the  $+1\sigma$  and  $-1\sigma$  values. For the  $E/p$  fits in the  $W$  boson sample, we reduce the effect of finite template statistics by fitting  $-\ln \mathcal{L}$  to a parabola, and extracting the best-fit value and the uncertainty from this parabola.

### III. DETECTOR AND MODEL

The CDF II detector [26,28] is well suited for the  $m_W$  measurement. Its high-resolution tracker and calorimeter measure individual charged lepton momenta from  $W$  and  $Z$  boson decays with a resolution of  $\approx 2\%$ . It has similar acceptance and resolution for central electrons and muons, giving the two channels similar weight in a combined mass measurement.

#### A. Detector components

The CDF II detector (Fig. 6) is a multipurpose detector consisting of an inner silicon tracker designed to measure the production vertex of charged particles with high precision, an outer tracking drift chamber to measure charged particle momenta, a solenoid to provide a uniform 1.4 T magnetic field inside the trackers, electromagnetic calorimeters to contain and measure electron and photon showers, hadronic calorimeters for hadron energy measurements, and a muon system to detect muons escaping the calorimeters. The detector information is read out online and saved for later analysis when event topologies consistent with a particular physics process (or class of processes) are selected. The readout decision is made with a fast three-level trigger system that has high efficiency for selecting the  $W$  and  $Z$  bosons to be used in the offline analysis.

#### 1. Tracking system

The silicon tracker (Fig. 7) consists of three separate detectors: Layer 00, SVX II, and ISL. Layer 00 is a single layer of 300  $\mu\text{m}$  thick sensors attached to the beam pipe at a radius of 1.3 cm. Five additional layers of sensors at radii ranging from 2.5 cm to 10.6 cm comprise SVX II. Surrounding these sensors are port cards, which transport deposited charge information from the silicon wafers to the readout system. The intermediate silicon layers (ISL) are located at radii of 20.2 cm and 29.1 cm. The SVX II is segmented longitudinally into three barrels in the region  $|z| < 45$  cm. This covers the  $p\bar{p}$  interaction region, which is well approximated by a Gaussian distribution with  $\sigma_z \approx 30$  cm. We do not use the silicon measurements in this analysis, though we model the tracker’s effects on leptons and photons (Sec. III B).

An open-cell drift chamber, the central outer tracker (COT) [29], surrounds the silicon tracker and covers the region  $|z| < 155$  cm ( $|\eta| \lesssim 1$ ) and  $40 \text{ cm} < r < 137$  cm. The COT consists of eight concentric “superlayers,” separated azimuthally into cells. Each cell contains 12 sense wires to measure the ionization produced by a charged particle in the ambient argon-ethane gas mixture. The superlayers alternate between a purely axial configuration, with sense wires parallel to the beam line, and a small-angle stereo configuration, with sense wires at a  $2^\circ$  angle relative to the  $z$  axis.

FIG. 6. A cut-away view of a section of the CDF detector. The slice is along the  $y$ -axis at  $x = 0$  cm.

The sense wires are strung from end to end in  $z$  and held under tension at each aluminum end plate (Fig. 8). The wires are azimuthally sandwiched by field sheets, which provide a 1.9 kV/cm electric field. All cells are rotated at a  $35^\circ$  angle relative to a radial line, such that the ionized electrons travel approximately azimuthally to the wire under the combined influence of the local electric field and the global magnetic field from the solenoid.

Within a given cell the sense wires are slightly off-center relative to the field sheets. In addition, the sense wires and field sheets sag under the influence of gravity, with the field sheets sagging more due to their larger masses. These effects cause a small electrostatic deflection of the sense wires toward a particular field sheet. To prevent the relative deflection of sense wires within a cell, a support rod connects the sense wires at the center of the detector. The support rod results in a small ( $\approx 2$  mm) region at  $z = 0$  cm where charged particles are not measured.

FIG. 7 (color online). End view of the silicon detector. The innermost layer (Layer 00) is attached to the beam pipe, and is surrounded by five concentric layers of silicon wafers (SVX II). The outermost layers are the intermediate silicon layers (ISL), which sit just inside the outer tracking chamber.

Between the solenoid and the COT is a time-of-flight system (TOF) consisting of scintillator bars that precisely measure the time of incidence of charged particles. From this measurement and the tracker information, a particle's velocity and mass can be inferred. The TOF is not utilized in this analysis.

### 2. Calorimeter system

The CDF calorimeter is segmented radially into electromagnetic and hadronic sections. The central calorimeter covers  $|\eta| < 1.1$  and is split at the center into two separate barrels covering  $+\eta$  and  $-\eta$ . Each barrel consists of 24 azimuthal “wedges” of size 0.26 radians ( $15^\circ$ ) with ten projective towers of size  $\Delta\eta \approx 0.11$ . To allow a pathway for the solenoid cryogenic tubes, a two-tower region is removed, corresponding to  $0.77 < \eta < 1.0$ ,  $75^\circ < \phi < 90^\circ$ , and  $z > 193$  cm. The forward calorimeter covers  $1.1 < |\eta| < 3.6$ , filling the forward gaps with a plug shape (Fig. 6).

FIG. 8 (color online). End view of a section of a central outer tracker (COT) end plate. The COT consists of eight concentric “superlayers,” separated azimuthally into cells, each containing 12 sense wires and sandwiched by field sheets. The end plates contain precision-machined slots where each cell’s sense wires and field sheets are held under tension. The radius at the center of each superlayer is shown in cm.

The central electromagnetic calorimeter [30] has a thickness of 18 radiation lengths, consisting of 31 radial scintillator layers interleaved with 30 layers of lead-aluminum plates. At a radius of 184 cm electromagnetic showers have traversed about six radiation lengths (including the solenoidal coil) and have their maximum energy deposition. At this radius finely segmented strip and wire chambers (CES) measure the energy deposition with a position resolution of  $\approx 2$  mm.

The local shower position in the azimuthal direction in the tower is denoted as CES  $x$ , which ranges from  $-24.1$  cm to  $24.1$  cm. The wire chambers extend only to  $|x| \leq 22.5$  cm, and for  $|x| > 23.1$  cm no energy measurements are made. In this region wavelength shifters read out the light from the scintillator, and steel and foam separate the towers. Light follows a waveguide to a phototube positioned at the back end of the hadronic calorimeter.

Parallel to the beam line, the position at shower maximum is denoted CES  $z$ . The strip chambers extend from 6 to 239 cm in  $|z|$ , and there is no scintillator for  $|z| < 4.2$  cm, where the two calorimeter barrels meet.

The central hadronic calorimeter [31] is separated into a central region ( $|\eta| < 0.6$ ) with 32 longitudinal layers of scintillator sandwiched with steel and a forward “wall” calorimeter ( $0.6 < |\eta| < 1.1$ ) with 15 such layers. These calorimeters have thicknesses of  $\approx 4.5$  interaction lengths.

The plug calorimeter [32] has a comparable design to the central calorimeter with scintillator-lead electromagnetic calorimeters and scintillator-steel hadronic calorimeter compartments. The  $\phi$  segmentation is 0.13 radians up to  $|\eta| = 2.1$ , and then broadens to 0.26 radians. The two farthest forward plug towers cover the  $|\eta|$  regions 2.6–3.0 and 3.0–3.6, while the remaining towers have a size of  $\Delta\eta = 0.1$ .

### 3. Muon detectors

The muon systems relevant for the  $W$  mass measurement cover the region  $|\eta| \leq 1$ . The central muon detector (CMU) and the central muon upgrade (CMP) cover  $|\eta| \leq 0.6$ , while the central muon extension (CMX) covers  $0.6 < |\eta| \leq 1$ .

The CMU detector [33] is located at the outer edge of the central hadronic calorimeter, 347 cm from the  $z$  axis. The CMU is segmented into  $15^\circ$  azimuthal wedges containing four layers of proportional drift chambers that cover  $12.6^\circ$ . The maximum drift time within a chamber is 800 ns, about twice as long as the 396 ns spacing between  $p\bar{p}$  crossings. CMU information must therefore be combined with reconstructed COT particle tracks to determine the appropriate  $p\bar{p}$  crossing.

Because the total thickness of the central calorimeter is about five interaction lengths, approximately 0.5% of high-momentum pions reach the CMU. To reduce this background, the CMP detector is located behind an additional 60 cm of steel. The CMP has a similar construction to the CMU, with the exception that wider drift chambers are used to cover the same solid angle, resulting in a maximum drift time of  $1.8 \mu\text{s}$  rather than 800 ns.

The CMX detector [34] consists of eight drift chamber layers beyond both the calorimeter and the steel detector support structure (6–10 interaction lengths). The CMX  $\phi$  regions used in this analysis are  $-45^\circ < \phi < 75^\circ$  and  $105^\circ < \phi < 225^\circ$ . New detectors for Run II cover much of the remaining  $\phi$  region, but were not fully commissioned for the data-taking period of this analysis. Scintillator detectors at the inner and outer surfaces of the CMX provide timing information to the trigger to separate collision particles from other sources such as beam halo or cosmic rays.

#### 4. Trigger system

The trigger consists of three stages with progressively greater sophistication of event reconstruction. The first stage is hardware based, the second a mix of hardware and software, and the third a farm of processors performing full event reconstruction.

The first trigger stage, level 1, includes tracker, calorimeter, and muon reconstruction. The charged particle track reconstruction is performed with the extremely fast tracker (XFT) [35] based on the four axial COT superlayers. A track segment is reconstructed in a given superlayer if at least 11 of the 12 sense wires [36] in a wide road have charge deposition above a given threshold (“hits”). The list of segments from the full tracker is compared to predefined groups of segments expected from charged particles above a given momentum threshold. When matches are found, track candidates are created and passed to the track extrapolator [37]. The track extrapolator determines the expected  $\phi$  positions of the tracks in the calorimeter and muon detectors, for the purpose of forming electron and muon candidates.

The calorimeter reconstruction at level 1 defines separate electromagnetic and hadronic “trigger towers” as tower pairs adjacent in  $\eta$ . The tower  $p_T$  is calculated assuming a collision vertex  $z = 0$  and an electron candidate is formed if the ratio of hadronic to electromagnetic energy (Had/EM) in a trigger tower is less than 1/8. The high-momentum electron trigger used in this analysis requires a level 1 trigger tower with electromagnetic  $p_T > 8$  GeV matched to a track with  $p_T > 8$  GeV, and drops the Had/EM requirement for electromagnetic  $p_T > 14$  GeV.

Level 1 muon reconstruction includes a  $p_T$  estimate within the CMU and CMX chambers from the relative timing of the hits in different layers. The CMU track segments are combined with reconstructed CMP track segments to create “CMUP” muon candidates. For the majority of the data CMX candidates also require local scintillator detectors hits consistent with particles originating from the collision. For our  $W$  and  $Z$  boson samples we use a muon trigger that requires CMU or CMX  $p_T > 6$  GeV matched to an XFT track with  $p_T > 4$  GeV (CMUP) or  $p_T > 8$  GeV (CMX).

The level 2 calorimeter reconstruction uses a more sophisticated clustering algorithm for electromagnetic objects. This improves energy measurement resolution and allows a higher threshold ( $p_T > 16$  GeV) to be applied. To reduce rates, the XFT track requirement for CMUP candidates was raised to  $p_T > 8$  GeV for most of the data-taking period.

At level 3, approximately 300 dual processor computers allow full track pattern recognition, muon reconstruction, and calorimeter clustering. Variables used to select electrons at level 3 are the lateral shower profile,  $L_{\text{shr}}$  (Sec. IV B), and the distance between CES  $z$  and the  $z$  position of the track extrapolated to the CES ( $\Delta z$ ). The  $L_{\text{shr}}$

variable quantifies the difference between the measured energies of towers neighboring the electron in  $\eta$  and the expected energies determined from electron test beam data. The trigger requirements of  $L_{\text{shr}} < 0.4$  and  $|\Delta z| < 8$  cm are  $\approx 100\%$  efficient for electrons from  $W$  and  $Z$  boson decays. The high-momentum electron trigger also requires electromagnetic  $p_T > 18$  GeV and track  $p_T > 9$  GeV. For efficiency studies we use a separate trigger that requires electromagnetic  $p_T > 25$  GeV and  $\not{p}_T^{L3} > 25$  GeV, but has no quality requirements at level 3 and no trigger track requirements. At level 3,  $\vec{p}_T^{L3}$  is defined as the negative of the vector sum of the transverse momenta in all calorimeter towers. The high-momentum muon trigger requires a COT track with  $p_T > 18$  GeV matched to a CMUP or CMX track segment.

#### 5. Luminosity detector

The small-angle Cherenkov luminosity counters [38] are used to measure the instantaneous and integrated luminosity of our data samples. The luminosity counters consist of two modules installed around the beam pipe at each end of the detector, providing coverage in the regions  $3.6 < |\eta| < 4.6$ . Each module contains 48 conical gas Cherenkov counters pointing to the collision region. Signals in both luminosity counter modules coinciding in time with the bunch crossing are used to measure the instantaneous luminosity and to trigger collision events. Events collected with this trigger, known as “minimum bias” events, are used to study the detector response to generic inelastic  $p\bar{p}$  collisions (Sec. VII).

#### B. Detector model

We use a parametrized model of the detector response to electrons, muons, and the hadronic recoil. The model is incorporated into a custom fast simulation that includes lepton and recoil reconstruction, event selection, and fit template generation. The simulation provides both flexibility in determining the effects of various inputs, and computing speed to allow frequent high-statistics studies. A sample of  $\mathcal{O}(10^7)$  events can be generated using a single-processor machine in 1 d. This is several orders of magnitude more than the  $\mathcal{O}(10^3)$  events that can be produced with the standard GEANT-based CDF simulation [39,40].

We describe in this section the simulation of electrons and muons. Fits to the data that determine the values of some of the model parameters are described in Secs. V and VI. The detector model of hadronic recoil response and resolution is discussed in Sec. VII.

The model components common to muons and electrons are ionization energy loss and multiple scattering in the beam pipe and tracker volume, parametrized track hit resolutions and efficiencies, and track reconstruction. We describe these components in the muon simulation overview, and then discuss the electron- and photon-specific simulation.

### 1. Muon simulation

Muon and electron tracks are reconstructed using only COT hit and beam position information (Sec. IV). Thus, the simulation of the silicon detector consists entirely of energy loss and multiple scattering. In the COT, hit resolutions and efficiencies are additionally simulated, and track reconstruction is performed. The total measured muon EM calorimeter energy is simulated by combining the minimum-ionizing energy deposition with energy from final-state photon radiation (Sec. IX D) and the recoil and underlying event [41]. Finally, the detector fiduciality of muons is calculated using a map of the muon detector geometry as a function of  $\eta$  and  $\phi$ . The map is extracted from a full GEANT-based simulation of the CDF II detector [39,40].

*Ionization energy loss.*—The differential ionization energy loss of muons and electrons in the tracking system is simulated according to the Bethe-Bloch equation [42]:

$$-\frac{dE}{dx} = \frac{KZ}{A\beta^2} \left[ \frac{1}{2} \ln \frac{2m_e\beta^2 T_{\max}}{(1-\beta^2)I^2} - \beta^2 - \frac{\delta}{2} \right], \quad (6)$$

where  $K = 4\pi N_A r_e^2 m_e$ ,  $N_A$  is Avogadro's number,  $r_e$  is the classical electron radius,  $Z(A)$  is the atomic (mass) number,  $\beta$  is the particle velocity,  $I$  is the mean excitation energy,  $T_{\max}$  is the maximum kinematic energy that can be transferred to a free electron in a single collision, and  $\delta$  is the material-dependent density effect as a function of  $\beta$  [42]. When calculating the effect of  $\delta$ , we take the material to be silicon throughout.

To calculate muon energy loss in the material upstream of the COT ( $r < 40$  cm), we use a three-dimensional lookup table of the material properties of the beam pipe, the silicon detector, and the wall of the aluminum can at the inner radius of the COT. The lookup table determines the appropriate  $Z/A$  and  $I$  values, along with the radiation length  $X_0$  (Appendix), for each of 32 radial layers. Except for the inner and outer layers, the map is finely segmented longitudinally and in azimuth to capture the material variation in the silicon detector [43]. Inside the COT fiducial volume we calculate the energy loss between each of the 96 radial sense wires.

The energy-loss model is tuned using the data. We apply a global correction factor of 0.94 to the calculated energy loss in the material upstream of the COT in order to obtain a  $J/\psi \rightarrow \mu\mu$  mass measurement that is independent of the mean inverse momentum of the decay muons (Sec. V B 3).

*Multiple Coulomb scattering.*—Multiple Coulomb scattering in the beam pipe, silicon detector, and COT affects the resolution of the reconstructed track parameters for low-momentum tracks. We model the scattering using a Gaussian distribution for 98% of the scatters [44] with an angular resolution  $\sigma_\theta$  defined by

$$\sigma_\theta = \frac{13.6 \text{ MeV}}{\beta p} \sqrt{x/X_0}, \quad (7)$$

where  $x$  is the thickness of the layer and  $X_0$  is the layer's radiation length (Sec. III B 2). Simulation of multiple scattering is implemented for each radial layer of the three-dimensional lookup table and between each COT layer.

Based on the results of low-energy muon scattering data [45], we model the non-Gaussian wide-angle scatters by increasing  $\sigma_\theta$  by a factor of 3.8 for 2% of the scatters.

*COT simulation and reconstruction.*—The charged track measurement is modeled with a full hit-level simulation of the charge deposition in the COT and a helical track fit. The parameter resolution of reconstructed tracks is affected by the individual hit resolution, and by the distribution of the number of hits ( $N_{\text{hit}}$ ) used in the fit [46].

We tune the COT hit resolution using the width of the  $Y \rightarrow \mu\mu$  mass distribution reconstructed with non-beam-constrained tracks. The tuned value of  $[150 \pm 3(\text{stat})] \mu\text{m}$  is consistent with the  $149 \mu\text{m}$  root-mean-square (RMS) of the observed hit residual distribution for the muon tracks in  $Z \rightarrow \mu\mu$  data. We use a  $150 \mu\text{m}$  hit resolution for the simulation of the  $Y$ ,  $W$ , and  $Z$  bosons.

We use a dual-resolution model to describe the narrower mass peak in the high-statistics  $J/\psi \rightarrow \mu\mu$  sample, where the muons generally have lower momenta than the other samples. The  $J/\psi$  mass peak width is particularly sensitive to multiple scattering and relative energy loss, and our hit-resolution model compensates for any mismodeling that affects the peak width. We find that a single-hit resolution of  $155 \mu\text{m}$  applied to 70% of the tracks and  $175 \mu\text{m}$  applied to the remaining 30% adequately describes the width and line shape of the  $J/\psi \rightarrow \mu\mu$  mass peak.

To describe the  $N_{\text{hit}}$  distribution, we use a dual-hit-efficiency model, the larger one applied to the majority of the tracks. The lower efficiency accounts for events with high COT occupancy, where fewer hits are attached to reconstructed tracks. The two parameters are tuned to match the mean and RMS of the data  $N_{\text{hit}}$  distributions. We independently tune these parameters for the  $J/\psi$  sample, the  $Y$  sample, and the  $W$  and  $Z$  boson samples.

COT hit positions from a charged track are used to reconstruct a helix with a  $\chi^2$ -minimization procedure. The axial helix parameters [47] are the impact parameter with respect to the nominal beam position,  $d_0$ , the azimuthal angle at the closest approach to the beam,  $\phi_0$ , and the curvature of the track,  $c$ , defined to be  $(2R)^{-1}$ , where  $R$  is the radius of curvature. The stereo helix parameters are the longitudinal position at the closest approach to the beam,  $z_0$ , and the cotangent of the polar angle,  $\cot\theta$ .

When optimizing resolution of lepton tracks from prompt resonance decays, we constrain the helix to originate from the location of the beam. The transverse size of the beam is  $\approx 30 \mu\text{m}$  at  $z = 0$  cm and increases to  $50\text{--}60 \mu\text{m}$  at  $|z| = 40$  cm [48]. For simplicity we assume an average beam size of  $[39 \pm 3(\text{stat})] \mu\text{m}$ , which is determined from a fit to the width of the  $Z \rightarrow \mu\mu$  mass peak. The beam constraint improves the intrinsic fractional mo-

momentum resolution by about a factor of 3, to  $\delta p_T/p_T \approx 0.0005 p_T/\text{GeV}$ .

We perform a track fit on our simulated hits in the same manner as the data. The hits are first fit to a helix without a beam constraint; hits with large residuals ( $> 600 \mu\text{m}$ ) are dropped from the track (in order to remove spurious hits added in data pattern recognition); and the track is fit again with an optional beam constraint. This option is applied to prompt lepton tracks from  $W$  and  $Z$  boson decays, but not to tracks from  $J/\psi$  decays, approximately 20% of which are not prompt. The prompt muons from  $Y$  decays are fit twice, both with and without the beam constraint, as a consistency check.

*Calorimeter response.*—Muons deposit ionization energy in the calorimeter. We simulate a muon's EM energy deposition using a distribution taken from cosmic-ray muons passing through the center of the detector, in events with no other track activity. An additional contribution comes from energy flow into the calorimeter from the underlying event [41]. We model this energy using a distribution taken from  $W \rightarrow \mu\nu$  data events, using towers separated in azimuth from the muon.

Muons with a CES  $z$  position within 1.58 cm of a tower boundary typically deposit energy in two calorimeter towers. We use this criterion in the simulation to apply the underlying event and final-state photon radiation (Sec. IX D) contributions for one or two towers. The simulated underlying event energy includes its dependence on  $u_{\parallel}$  and  $u_{\perp}$  (Fig. 5), and on the  $\eta$  position of the muon (Sec. VII B).

*Detector fiduciality.*—The CMUP and CMX muon systems do not have complete azimuthal or polar angle coverage. We create an  $\eta - \phi$  map of each muon detector's coverage using muons simulated [40] with a detector geometry based on GEANT [39]. We use the map in the fast simulation to determine the fiduciality of a muon at a given  $\eta - \phi$  position.

We incorporate the relative efficiency of the CMUP to CMX triggers in the fast simulation by matching the ratio of CMUP to CMX events in the  $W \rightarrow \mu\nu$  data (Sec. IV A).

## 2. Electron and photon simulation

The dominant calibration of the calorimeter energy measurement  $E$  of electrons uses their track momenta  $p$  and a fit to the peak of the  $E/p$  distribution. An additional calibration results from a mass fit to the  $Z$  boson resonance and reduces the calibration uncertainty by 20% relative to the  $E/p$  calibration alone.

The  $E/p$  method relies on an accurate modeling of radiative effects that reduce the track momentum measured in the COT. A given electron loses  $\approx 20\%$  of its energy through bremsstrahlung radiation in the silicon detector, and this process has the most significant impact on the  $E/p$  calibration. The total amount of silicon detector material is tuned with data using highly radiative electrons

(Sec. VI A). We additionally model processes that affect the shape of the  $E/p$  distribution: photon conversion in the tracker, energy loss in the solenoid and the time-of-flight system, electromagnetic calorimeter response and resolution, and energy loss into the hadronic calorimeter. The models of ionization energy loss and multiple scattering in the tracker, as well as the COT track simulation and reconstruction, are the same as for muons (Sec. III B 1).

*Bremsstrahlung.*—The differential cross section for an electron of energy  $E_e$  to radiate a photon of energy  $E_\gamma$  is given by the screened Bethe-Heitler equation [49] over most of the  $y \equiv E_\gamma/E_e$  spectrum. In terms of the material's radiation length  $X_0$ , the differential cross section for bremsstrahlung radiation is

$$\frac{d\sigma}{dy} = \frac{A}{N_A X_0 \rho} \left[ \left( \frac{4}{3} + C \right) \left( \frac{1}{y} - 1 \right) + y \right], \quad (8)$$

where  $C$  is a small material-dependent correction (Appendix). Figure 9 shows the integrated thickness of material upstream of the COT, in terms of radiation lengths, traversed by the reconstructed electron tracks in  $W \rightarrow e\nu$  data. The number of photons emitted per layer is given by

$$N_\gamma = \frac{x}{X_0} \left[ \left( \frac{4}{3} + C \right) (y_0 - \ln y_0 - 1) + \frac{1}{2} (1 - y_0)^2 \right], \quad (9)$$

where  $x$  is the thickness of the layer and  $y_0$  is a lower threshold introduced to avoid infrared divergences. We use  $y_0 = 10^{-4}$  [50] and determine  $C = 0.0253$  using the silicon atomic number  $Z = 14$ .

For each layer of the silicon or COT material, we use a Poisson distribution with mean  $N_\gamma$  to determine the number of photons radiated in that layer. For each radiated

FIG. 9. The distribution of material upstream of the COT traversed by reconstructed electron trajectories in  $W \rightarrow e\nu$  data events, in units of radiation lengths. The peaks at  $\approx 0.08$ ,  $\approx 0.13$ , and  $\approx 0.24$  correspond, respectively, to trajectories outside the silicon detector ( $|z| > 45$  cm), within the silicon detector, and crossing silicon barrels ( $|z| \approx 15, 45$  cm). The mean of the distribution is 19%.

photon, we calculate  $y$  from the spectrum in Eq. (8). To correct for inaccuracies of the screened Bethe-Heitler equation at the ends of the  $y$  spectrum, we apply a suppression factor if  $y \leq 0.005$  or  $y \geq 0.8$ .

For radiation of high-momentum photons ( $y \geq 0.8$ ), the approximation of complete screening of the nuclear electromagnetic field by the atomic electrons breaks down. In this region, the full Bethe-Heitler equation for incomplete screening [49] must be used. We implement this correction by removing generated photons in the high- $y$  region such that we match the reduced cross section from incomplete screening.

Two effects reduce the cross section for low-momentum photon radiation [51]: multiple scattering and Compton scattering. Multiple Coulomb scattering suppresses long-distance interactions, and the resulting Landau-Pomeranchuk-Migdal (LPM) suppression [52] in low-momentum radiation can be expressed in terms of the Bethe-Heitler cross section [53]:

$$S_{\text{LPM}} \equiv \frac{d\sigma_{\text{LPM}}/dy}{d\sigma_{\text{BH}}/dy} = \sqrt{\frac{E_{\text{LPM}}}{E_e} \frac{y}{(1-y)}}, \quad (10)$$

where  $E_{\text{LPM}}$  depends on the material. We use  $E_{\text{LPM}} = 72$  TeV, appropriate for silicon, and apply the suppression when  $S_{\text{LPM}} < 1$ .

Radiated photons scatter off the atomic electrons, and destructive interference of low-momentum photons suppresses this radiation [54]. The suppression factor is

$$S_{\text{Compton}} = \frac{y^2}{y^2 + E_p^2/E_e^2}, \quad (11)$$

where  $E_p = \gamma\omega_p$  is 2.4 MeV for a 40 GeV electron in silicon, using the silicon plasma frequency  $\omega_p$ , and  $\gamma$  is the Lorentz factor.

In any given simulated event, the product of  $S_{\text{LPM}}$  and  $S_{\text{Compton}}$  provides the probability that a photon generated from the screened Bethe-Heitler equation with  $y \leq 0.005$  survives the low-momentum suppression. For a 40 GeV electron radiating a 20 MeV (8 MeV) photon, the suppression factors are  $S_{\text{LPM}} = 0.95(0.60)$  and  $S_{\text{Compton}} = 0.99(0.92)$ . Our simulated  $y$  spectrum from  $W$  boson decay electrons reproduces the spectrum obtained by a GEANT [39] simulation.

*Photon conversion.*—Photons can convert to an electron-positron pair by interacting with the tracker material. The differential cross section for a photon of energy  $E_\gamma \geq 1$  GeV to convert into an electron with energy  $E_e$  is given by the screened Bethe-Heitler equation [49]:

$$\frac{d\sigma}{dy} = \frac{A}{N_A X_0 \rho} [1 - (4/3 + C)y(1-y)], \quad (12)$$

where  $y = E_e/E_\gamma$ . Integrating over  $y$  and multiplying by  $\rho x N_A/A$  gives the total cross section, from which we obtain the following conversion probability at high photon

energy:

$$P_{\gamma \rightarrow e^+e^-}(E_\gamma \rightarrow \infty) = 1 - e^{-(7/9 - C/6)x/X_0}. \quad (13)$$

We parametrize the cross section as a function of photon energy using the tables for photon cross sections in silicon given in [55]. We apply the ratio shown in Fig. 10 to the high-energy cross section when calculating the conversion probability.

For each radiated photon upstream of the COT, we integrate the material between the radiation point and the COT inner can. If the photon converts, we take the conversion point to be halfway between the radiation point and the inner can. If the photon does not convert before the COT, we integrate the material in the COT and take a converting photon to convert halfway through the COT.

We use the conversion electron momentum spectrum from Eq. (12), ignoring the small effect of the  $C$  term on the shape. If a radiated photon has high momentum, a conversion electron's measured momentum can be larger than that of the electron from the  $W$  boson decay. To mimic the offline reconstruction, we assign the track from the highest momentum electron to the electron cluster.

*Compton scattering.*—The cross section for a low-momentum photon to scatter off an electron is similar to that of conversion into an  $e^+e^-$  pair. The differential cross section with respect to the photon fractional energy loss  $y$  can be approximated as (Appendix)

$$\frac{d\sigma}{dy} \propto 1/y + y. \quad (14)$$

Using a lower bound of  $y = 0.001$ , this spectrum approximates the Compton energy-loss distribution for photons radiated from electrons from  $W$  boson decays.

We calculate the total cross section in terms of the pair-production cross section using the tables for photon inter-

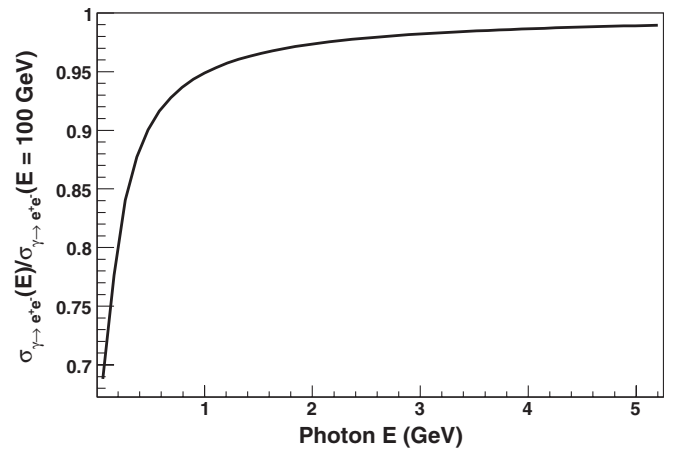

FIG. 10. The ratio of the photon conversion cross section at a given photon energy to the cross section at  $E_\gamma = 100$  GeV [55]. We use this function to scale down the cross section obtained from the Bethe-Heitler equation [Eq. (13)] [49].

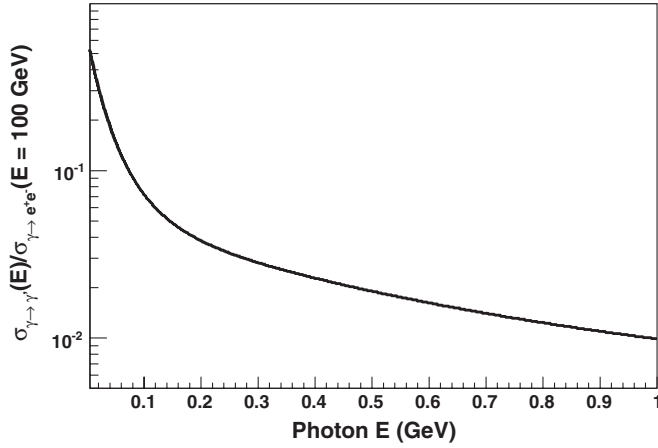

FIG. 11. The ratio of the Compton scattering cross section at a given photon energy to the pair-production cross section at  $E_\gamma = 100$  GeV [55]. This ratio is applicable for photons traversing silicon.

actions in silicon in [55]. The ratio of cross sections as a function of energy is parametrized as (Fig. 11)

$$R_{\text{Compton}} \equiv \frac{\sigma_{\gamma \rightarrow \gamma'}}{\sigma_{\gamma \rightarrow e^+e^-}(E_\gamma \rightarrow \infty)} = e^{F(E_\gamma)}, \quad (15)$$

where  $F(E_\gamma) = 2.35e^{-1.16E_\gamma} + 2.42e^{-15.8E_\gamma} - 5.21 - 0.151E_\gamma$ , with  $E_\gamma$  in GeV, and  $\gamma$  and  $\gamma'$  are the initial- and final-state photons, respectively. We thus use the following Compton scattering probability per layer:

$$P_{\gamma \rightarrow \gamma'} = R_{\text{Compton}}(7/9 - C/6)x/X_0. \quad (16)$$

*Energy loss in solenoid.*—After exiting the tracker electrons and photons travel through the TOF system and the solenoid. These systems have thicknesses of  $\approx 10\%$  and  $\approx 85\%$  of a radiation length, respectively. With this much material it becomes prohibitive to model individual radiative processes, and we instead use a parametrized energy-loss model determined from a GEANT simulation [39]. The energy loss is defined as the difference in energy of a single particle entering the TOF and the total energy of particles exiting the solenoid.

Figure 12 shows the mean energy loss as a function of  $\log_{10}(p_T/\text{GeV})$  of the incoming particle for both photons and electrons. Electrons lose more energy than photons due to their ionization of the material. Since electrons with  $p_T \lesssim 400$  MeV curve back to the center of the detector before exiting the solenoid, we do not parametrize energy loss in this energy region.

The energy-loss distribution at a given particle  $p_T$  is reasonably described by an exponential. We use this distribution, with a mean determined by Fig. 12, to model the energy loss of a given particle passing through the TOF and solenoid.

*Calorimeter response and fiduciality.*—The calorimeter simulation models the response of the electromagnetic

FIG. 12. The mean  $p_T$  loss as a function of  $\log_{10}(p_T/\text{GeV})$  for electrons with  $p_T > 400$  MeV (solid line) and photons (dashed line) traversing the time-of-flight system and solenoid.

calorimeter as a function of each particle's energy and position, and the fraction of shower energy leaking into the hadronic calorimeter.

The electromagnetic calorimeter response, or the average measured energy divided by the true particle energy entering the calorimeter, can depend on each particle's energy. Possible sources of this dependence are variations in light yield as a function of calorimeter depth, attenuation in the light guide from the scintillator to the phototube, or leakage of showering particles into the hadronic calorimeter. The mean fractional energy leakage into the hadronic calorimeter for particles exiting the tracker, determined using the GEANT-based calorimeter simulation, is shown as a function of  $\log_{10}(p_T/\text{GeV})$  in Fig. 13.

For a low- $p_T$  particle exiting the tracker, the distribution of energy loss into the hadronic calorimeter is adequately described by an exponential. For high- $p_T$  particles ( $\geq 10$  GeV), the distribution has a peak at nonzero values of energy loss. In this energy region we model the hadronic energy-loss fluctuations with the distributions shown in Fig. 13. Because a nonnegligible fraction of electrons lose a significant amount of energy (5–10%) in the hadronic calorimeter, it is important to model the energy-loss spectrum in addition to the mean hadronic energy loss.

To correct for any unaccounted dependence of the response on incoming particle energy, we use an empirical model of response that increases linearly with particle  $p_T$ :

$$R_{\text{EM}}(p_T) = S_E[1 + \xi(p_T/\text{GeV} - 39)]. \quad (17)$$

We determine the slope parameter  $\xi = [6 \pm 7(\text{stat})] \times 10^{-5}$  using fits to the electron  $E/p$  distribution as a function of  $p_T$  in  $W \rightarrow e\nu$  and  $Z \rightarrow ee$  events (Sec. VI). The inclusive  $E/p$  distribution from  $W \rightarrow e\nu$  events is used to calibrate the absolute response  $S_E$ . Since electrons in this sample have a mean  $p_T$  of 39 GeV, the fitted values for  $S_E$

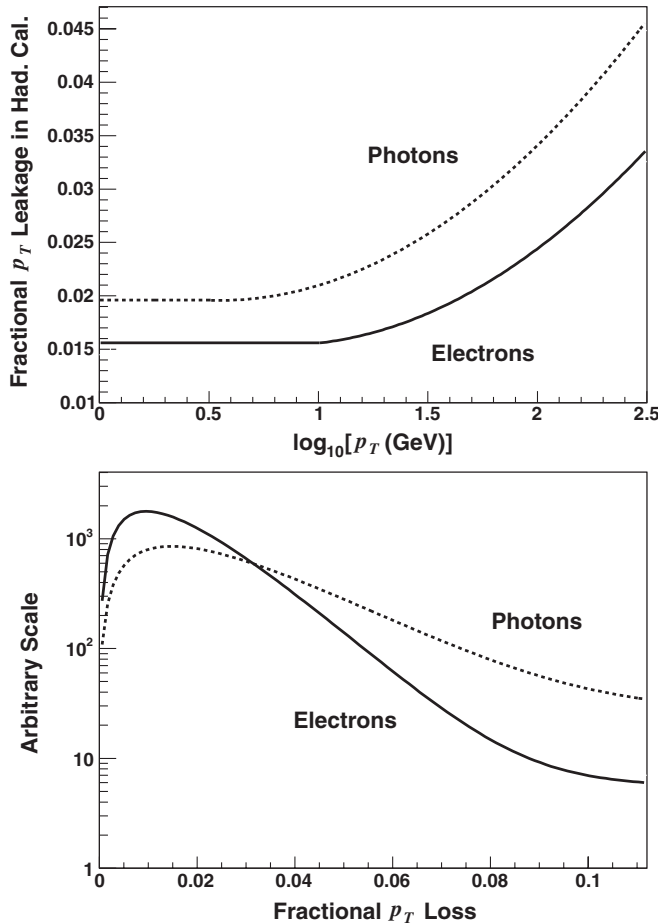

FIG. 13. The electron (solid line) and photon (dashed line)  $p_T$  leakage into the hadronic calorimeter. Top: The mean  $p_T$  leakage as a function of  $\log_{10}(p_T/\text{GeV})$ . Bottom: The distributions of  $p_T$  leakage for high- $p_T$  (> 10 GeV) photons and electrons.

and  $\xi$  are uncorrelated. The parameter  $\xi$  describes the “nonlinearity” of the calorimeter response.

Light attenuation in the scintillator results in nonuniform response as a function of distance from the wavelength-shifting light guides. The attenuation function was measured using test beam data at construction, and aging effects are measured *in situ* using electrons from  $W$  boson decays. The function is parametrized as a quadratic function of the CES  $x$  position within a tower and corresponds to a reduction in response of  $\approx 10\%$  at the edge of the tower. We simulate the light attenuation by reducing the energy deposited by each particle according to this function, evaluated at the particle’s CES  $x$  position.

To improve measurement resolution in data, we correct for attenuation effects by applying the inverse of the quadratic attenuation function to the measured EM energy. We match this procedure in the simulation.

The EM calorimeter response drops rapidly as a particle crosses the edge of the scintillator and into the dead region between towers [30]. We take the calorimeter to have zero

response for any particle with  $|\text{CES } x| > 23.1$  cm or  $|\text{CES } z| < 4.2$  cm. For the  $m_W$  measurement we only use high-energy electrons far from the dead regions (Sec. IV B).

We apply the following smearing to the calorimeter cluster energy:

$$\sigma_E/E = \sqrt{0.135^2/p_T + \kappa^2}, \quad (18)$$

where the constant term  $\kappa$  is determined to be  $[0.89 \pm 0.06(\text{stat}) \pm 0.13(\text{sys})]\%$  from a fit to the width of the electron  $E/p$  peak in  $W$  boson decays [56]. We find further energy smearing is necessary to model the multiparticle energy clusters populating the high- $E/p$  region. When a simulated  $W$  or  $Z$  decay electron radiates in the tracker, we apply an additional fractional resolution of  $\kappa_\gamma = [8.3 \pm 2.2(\text{stat})]\%$  to each bremsstrahlung photon and conversion electron. This smearing contributes  $\approx 1.3\%$  to the effective constant term, and is determined from a fit to the width of the  $Z$  boson mass peak reconstructed from radiative electrons ( $E/p > 1.06$ ).

The final contribution to the electron cluster energy comes from the underlying event [41]. As with muons, we measure this energy distribution in  $W$  boson data as a function of  $u_{\parallel}$ ,  $u_{\perp}$ , and electron  $\eta$  (Sec. VII B). These measurements are incorporated in the simulation.

## IV. $W$ BOSON SELECTION

The  $W$  boson samples are collected with triggers requiring at least one central ( $|\eta| \leq 1$ ) lepton candidate in the event. A narrow kinematic region is defined for  $W$  boson selection:  $30 \text{ GeV} < \text{lepton } p_T < 55 \text{ GeV}$ ;  $30 \text{ GeV} < \not{p}_T < 55 \text{ GeV}$ ;  $60 \text{ GeV} < m_T(l, \not{p}_T) < 100 \text{ GeV}$ ; and  $u_T < 15 \text{ GeV}$ . This selection results in low background while retaining events with precise  $m_W$  information. Additional background rejection is achieved through event selection targeting the removal of  $Z$  boson decays to leptons. To minimize bias, lepton selection criteria are required to have high efficiency or to be explicitly modeled by our fast simulation.

### A. $W \rightarrow \mu\nu$ selection

Muons are identified based on their reconstructed COT track quality and production vertex, minimum-ionizing energy deposited in the calorimeter, and the consistency of the track segments reconstructed in the muon chambers with the COT tracks.

All charged lepton candidates from  $W$  and  $Z$  boson decay are required to have fully fiducial central ( $|z_0| < 60$  cm) COT tracks with at least 5 hits on each of  $\geq 3$  axial superlayers and  $\geq 3$  small-angle stereo superlayers. For muon candidates we remove background from decays of long-lived hadrons to muons (“decays in flight”) by requiring the track impact parameter to be small ( $|d_0| < 1$  mm) and the track fit quality to be good ( $\chi^2/\text{dof} < 3$ ,

where dof refers to the  $N_{\text{hits}} - 5$  degrees of freedom in the unconstrained COT track fit). After this initial selection, the COT track parameters are updated with an additional constraint to the transverse position of the beam, which has a size of  $\approx 30 \mu\text{m}$  in the luminous region. The beam constraint results in a factor of  $\approx 3$  improvement in momentum resolution for muons from  $W$  boson decays.

Each muon candidate's COT track is extrapolated to the calorimeter and its energy depositions in the electromagnetic and hadronic calorimeters are separately measured. Muons near a tower edge in the  $z$  direction cross two calorimeter towers, and those tower energies are combined to determine the muon's total energy deposition. We require the muon's electromagnetic energy deposition  $E_{\text{EM}}$  to be less than 2 GeV and its hadronic energy deposition  $E_{\text{Had}}$  to be less than 6 GeV [26].

All  $W$  muon candidates must have a track segment in either the CMU and CMP detectors, or the CMX detector. COT tracks extrapolated to these detectors must have  $r - \phi$  positions that match to within 3, 5, or 6 cm of the CMU, CMP, or CMX track segment positions, respectively.

The  $Z/\gamma^* \rightarrow \mu\mu$  process presents a significant background to the  $W \rightarrow \mu\nu$  sample. We reduce this background by removing events with a second opposite-charge muon candidate passing the above selection, or passing the following looser set of criteria: an opposite-charge track with  $p_T > 10 \text{ GeV}$ ,  $|d_0| < 1 \text{ mm}$ ,  $\geq 2$  axial superlayers with  $\geq 5$  hits, and  $\geq 2(1)$  small-angle stereo superlayers with  $\geq 5$  hits for tracks fully (partially) fiducial to the COT;  $E_{\text{EM}} < 2 \text{ GeV}$  and  $E_{\text{Had}} < 6 \text{ GeV}$ ; and calorimeter isolation  $< 0.1$ . Calorimeter isolation is defined as the calorimeter  $p_T$  in an  $\eta - \phi$  cone of radius 0.4 surrounding the muon calorimeter towers, divided by the muon track  $p_T$ . For events with one identified  $W$  decay muon and a second muon candidate passing the looser criteria, the identified  $W$  decay muon must also have isolation  $< 0.1$  for the event to be rejected from the  $W$  boson sample. The full  $W$  boson sample, after kinematic selection and  $Z$  boson rejection, contains 51 128 events in  $(191 \pm 11) \text{ pb}^{-1}$  of data.

The identification efficiency of muons has a small dependence on the recoil in  $W \rightarrow \mu\nu$  and  $Z \rightarrow \mu\mu$  events, due primarily to the track  $\chi^2$  and  $d_0$  requirements. We measure this dependence using  $Z \rightarrow \mu\mu$  events, selected with one muon passing the  $W$  muon candidate criteria and a second ‘‘probe’’ muon identified as a track with  $p_T > 30 \text{ GeV}$ . The two muons must have opposite charge and reconstruct to an invariant mass in the 81–101 GeV range. The fraction of probe muons passing the additional  $W$  muon candidate selection criteria is shown in Fig. 14 as a function of net recoil energy along the muon direction ( $u_{\parallel}$ ). The observed dependence is parametrized as

$$\epsilon = a[1 + b(u_{\parallel} + |u_{\parallel}|)], \quad (19)$$

where  $a$  is a normalization factor that does not affect the  $m_W$  measurement and  $b = [-1.32 \pm 0.40(\text{stat})] \times 10^{-3}$ .

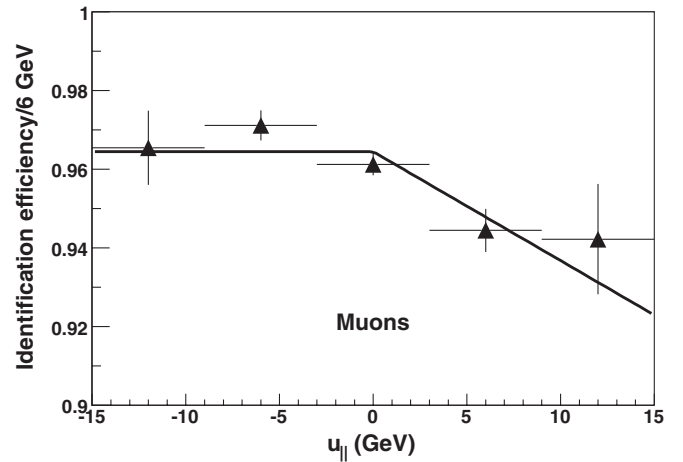

FIG. 14. The muon identification efficiency as a function of the recoil component in the direction of the muon ( $u_{\parallel}$ ).

We vary  $b$  by  $\pm 3\sigma$  in simulated data and fit for  $m_W$ . Assuming a linear variation of  $m_W$  with  $b$ , we derive uncertainties of  $\delta m_W = 1, 6,$  and  $13 \text{ MeV}$  for the  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits, respectively.

### B. $W \rightarrow e\nu$ selection

Electron identification uses information from the COT track quality and production vertex, the matching of the track to calorimeter energy and position, and the longitudinal and lateral calorimeter energy profiles.

An electron candidate's COT track has the same fiduciality and hit usage requirements as a muon candidate track, and utilizes the same beam-constrained track fit. The track is required to have  $p_T > 18 \text{ GeV}$ , a kinematic region where the trigger track-finding efficiency has no  $p_T$  dependence.

The clustering of showers in the CES produces an energy-weighted position at the electron shower maximum. We require the CES cluster to be well separated from the edges of the towers,  $|\text{CES } x| < 18 \text{ cm}$  and  $|\text{CES } z| > 9 \text{ cm}$ . The cluster  $z$  position is compared to the extrapolated track  $z$  position, and the difference is required to be less than 5 cm, consistent with the trigger requirement. The ratio of the measured calorimeter energy to the track momentum,  $E/p$ , must be less than 2.

Electrons are differentiated from hadrons by their high fraction of energy deposited in the electromagnetic calorimeter. The electron's EM energy is measured in two neighboring towers in  $\eta$ , while the energy collected in the hadronic calorimeter is measured in three towers. The ratio,  $E_{\text{Had}}/E_{\text{EM}}$ , is required to be less than 0.1. Only the EM calorimeter measurement is used to determine the electron's  $p_T$ .

An electron shower will typically be confined to a single tower, with a small amount of energy flowing into the nearest tower in  $\eta$ . We define an error-weighted difference between the observed and expected energies in the two

towers neighboring the electron in the  $\eta$  direction [57]:

$$L_{\text{shr}} = 0.14 \sum_i \frac{E_i^{\text{adj}} - E_i^{\text{exp}}}{\sqrt{0.14^2 E_i^{\text{adj}} + (\Delta E_i^{\text{exp}})^2}}, \quad (20)$$

where  $E_i^{\text{adj}}$  is the energy in a neighboring tower,  $E_i^{\text{exp}}$  is the expected energy contribution to that tower,  $\Delta E_i^{\text{exp}}$  is the RMS of the expected energy, energies are measured in GeV, and the sum is over the two neighboring towers. We require  $L_{\text{shr}} < 0.3$ , consistent with the trigger criterion (Sec. III A 4).

The  $Z \rightarrow ee$  background is highly suppressed by the  $u_T < 15$  GeV requirement for the  $W$  boson sample. Residual background results from electrons passing through dead calorimeter regions, which reduces  $u_T$  and increases  $\not{p}_T$ . We remove events from the  $W$  sample if a track with  $p_T > 20$  GeV and  $|d_0| < 0.3$  cm extrapolates to a calorimeter region with reduced response ( $|\text{CES } x| > 22$  cm or  $|\text{CES } z| < 6$  cm), and the track's calorimeter isolation is  $< 0.1$  (Sec. IV A). The full  $W \rightarrow e\nu$  selection results in a sample of 63 964 candidate events in  $(218 \pm 13)$   $\text{pb}^{-1}$  of integrated luminosity.

The track selection in the single-electron trigger (Sec. III A 4) results in an  $\eta$ -dependent trigger efficiency for reconstructed electrons (Fig. 15). We study this efficiency using  $W$  events selected with a trigger where the track requirements are replaced by a  $\not{p}_T$  threshold. The efficiency decreases as  $|\eta|$  decreases because the reduced path length reduces the ionization charge collected by each wire, thus reducing the single-hit efficiency. There is an additional decrease in efficiency due to the dead region at  $|z| \approx 2$  mm. Electrons crossing this region at track  $|\eta| = 0$  are not included in the efficiency plot, since we only measure electrons with  $|\text{CES } z| > 9$  cm. Thus, at  $|\eta| = 0$  there is no inefficiency due to the dead COT region, and the measured efficiency increases.

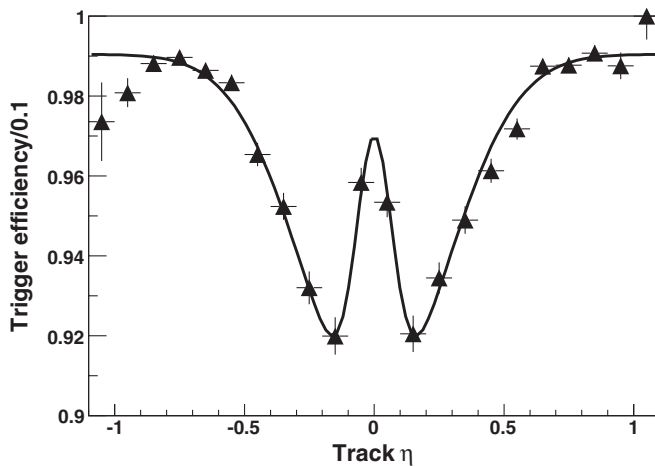

FIG. 15. The electron track trigger efficiency as a function of track  $\eta$ , for electrons identified in the calorimeter. The solid line shows the double-Gaussian parametrization of the data.

FIG. 16. The electron identification efficiency measured in  $Z \rightarrow ee$  data as a function of the recoil component in the direction of the electron ( $u_{\parallel}$ ). Background is subtracted using the number of like-charge lepton events observed at a given  $u_{\parallel}$ . The  $E/p < 2$  requirement is not included in this efficiency measurement.

We measure the  $u_{\parallel}$  dependence of the electron identification efficiency (Fig. 16) using  $Z \rightarrow ee$  events, selected with one electron passing the  $W$  electron candidate criteria and a second “probe” electron identified as an EM energy cluster with  $p_T > 30$  GeV, an associated track with  $p_T > 18$  GeV, and  $E/p < 2$ . Since the probe electron definition includes an  $E/p$  requirement, this cut is not included in the efficiency measurement. We instead study the unbiased  $E/p < 2$  efficiency by recalculating  $E$  and  $u_{\parallel}$  for towers separated in  $\phi$  from the identified electron in  $W \rightarrow e\nu$  events, and find no significant  $u_{\parallel}$  dependence in this efficiency. In the simulation we use  $b = 0 \pm 0.54 \times 10^{-3}$ , obtained by fitting the measured efficiencies to the function in Eq. (19).

We vary  $b$  by  $\pm 3\sigma$  in pseudoexperiments and assume linear variation of  $m_W$  with  $b$  to derive uncertainties of  $\delta m_W = 3, 5,$  and  $16$  MeV for the  $m_T, p_T,$  and  $\not{p}_T$  fits, respectively. Since  $b$  is measured with different data samples for the electron and muon channels, there is no correlation between the corresponding systematic uncertainties.

## V. TRACK MOMENTUM MEASUREMENT

Muon momenta are determined from helical fits to tracks reconstructed using COT information. The momentum resolution of prompt muons is improved by constraining the helix to originate from the transverse beam position. A given muon's transverse momentum is determined by the Lorentz equation,

$$mv^2/R = evB, \quad p_T = eB/(2|c|), \quad (21)$$

where  $B$  is the magnetic field,  $R$  is the radius of curvature,  $c \equiv q/(2R)$  is the curvature of the helix, and  $q$  is the muon

charge. The *a priori* momentum scale is determined by the measurements of the magnetic field and the radius of the tracker. At CDF,  $eB/2 = 2.11593 \times 10^{-3}$  GeV/cm, where  $B$  is measured using an NMR probe at a COT end plate. Measurements of the local field nonuniformities and tracker geometry were performed during construction and installation and are used to determine the positions of individual track hits. We find these measurements provide an *a priori* momentum scale accuracy of  $\approx 0.15\%$ .

We refine the momentum scale calibration with data. Using reconstructed cosmic-ray muon tracks, we align the relative positions of the tracker wires. Track-level corrections derived from  $W \rightarrow e\nu$  data reduce relative curvature bias between positive and negative particles. Finally, we perform an absolute calibration of the momentum scale using high-statistics data samples of  $J/\psi$ ,  $Y$ , and  $Z$  boson decays to muons. The final calibration is applied as a relative momentum correction  $\Delta p/p$  to the  $W$  boson data and has an accuracy of  $\approx 0.02\%$ .

### A. COT alignment

The COT contains 30240 sense wires for measuring the positions of charged particles passing through the detector. The position measurements rely on an accurate knowledge of the wire positions throughout the chamber. We determine these positions using a combination of alignment survey, computer modeling, and cosmic-ray muon data. Any remaining biases in track parameter measurements are studied with  $J/\psi \rightarrow \mu\mu$  and  $W \rightarrow e\nu$  data, from which final track-level corrections are derived.

After construction of the COT end plates, the position of each 12-wire cell was measured with an accuracy of  $\pm 13 \mu\text{m}$  using a coordinate measuring machine. The effect of the load of the wire plane and field sheets was modeled with a finite element analysis (FEA) and found to cause an end plate bend toward  $z = 0$  cm, with the maximum bend of  $\approx 6$  mm in the fifth superlayer [29]. An equivalent load was applied to the detector and further measurements found the FEA to be accurate to within  $\approx 20\%$ . The FEA results were scaled to match the measurements, and the positions determined from the FEA were set as the directly determined cell positions.

While each cell position determines the average positions of its 12 sense wires within the chamber, several effects create a nonlinear wire shape as a function of  $z$ . Gravity has the most significant effect, causing each wire to sag  $\approx 260 \mu\text{m}$  in  $y$  at  $z = 0$  cm. Electrostatic deflection toward the nearest field sheet occurs for cells where the sense wire is not centered between the field sheets. By construction, the wires are slightly offset within a cell; in addition, the gravitational sag of the field sheets is larger than that of the sense wires, resulting in an electrostatic deflection that partially counteracts the sag of the sense wires. Combined, the electrostatic effects cause a  $\phi$ -dependent wire shift that has a maximum of  $74 \mu\text{m}$  at

$\phi = 145^\circ$  and  $z = 0$  cm. The gravitational and electrostatic effects were combined to determine the best *a priori* estimate of the wire shapes.

Starting from the predicted cell and wire positions, we develop *in situ* corrections based on cosmic-ray muon data taken during  $p\bar{p}$  crossings with the single-muon trigger. The data are selected by requiring exactly two reconstructed tracks in the event, eliminating effects from overlapping hits from collision-induced particles. Since the two tracks on opposite sides of the COT result from a single cosmic-ray muon, we refit both tracks to a single helix and determine hit residuals with respect to this helix [58]. For each cell, we use the residuals to determine a tilt correction about its center, and a shift correction along the global azimuth (Fig. 17). We show the tilt and shift corrections for the inner superlayer of the west end plate in Fig. 18, after removing global corrections. We apply corrections to each cell of each superlayer in each end plate. In addition, we measure a relative east-west shift and include it in each cell's correction.

We combine the cell-based corrections with wire-based corrections for the shapes of the wires between the end plates. We measure these corrections as functions of  $z$  and radius  $R$  using the differences in the measured  $d_0$  and curvature parameters for the helix fits on opposite sides of the COT for a cosmic-ray muon. The corrections are applied as additional offsets  $\Delta\xi$  of the wires at  $z = 0$  cm, with a parabolic wire shape as a function of  $z$ . The corrections include a radial dependence,

$$\Delta\xi = -160 + 380(R/140) - 380(R/140)^2, \quad (22)$$

where  $R$  is measured in cm and  $\Delta\xi$  in  $\mu\text{m}$ . Figure 19 shows the gravitational and electrostatic shifts of a wire as a function of  $z$  at  $\phi = \pi$ , as well as the data-based correction at  $R = 130$  cm (the outer superlayer).

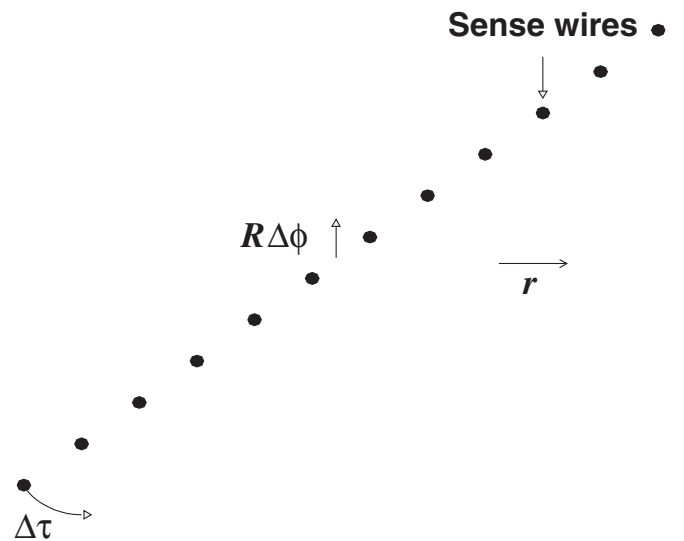

FIG. 17. The definitions of the local tilt ( $\Delta\tau$ ) and azimuthal shift ( $R\Delta\phi$ ) alignment corrections applied to each COT cell.

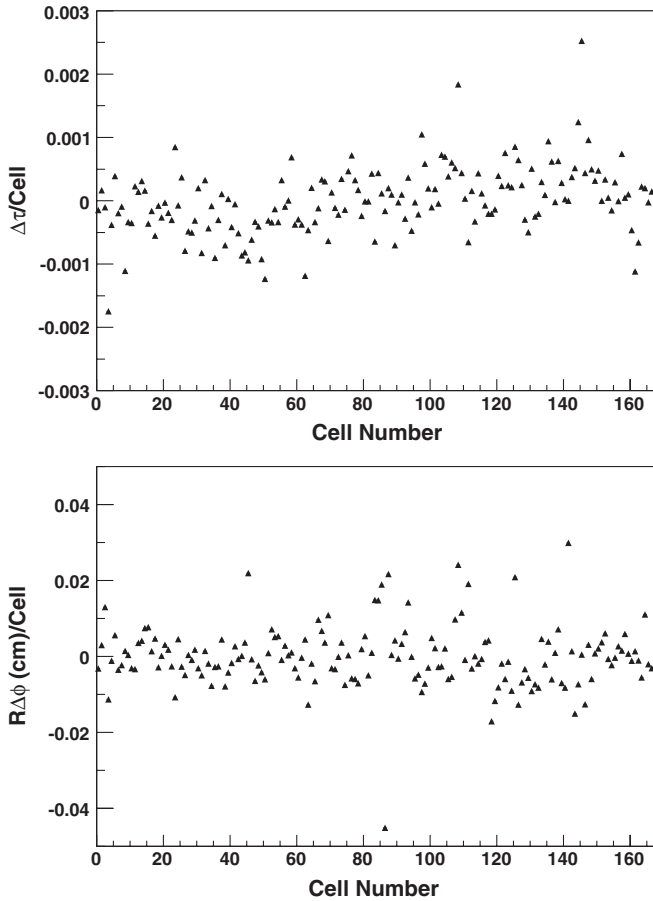

FIG. 18. The local tilt (top) and azimuthal shift (bottom) alignment corrections applied to each cell of the inner superlayer of the west end plate. Not shown are a global 0.0021 tilt correction and a small global rotation and shift of the COT that only redefines the axes.

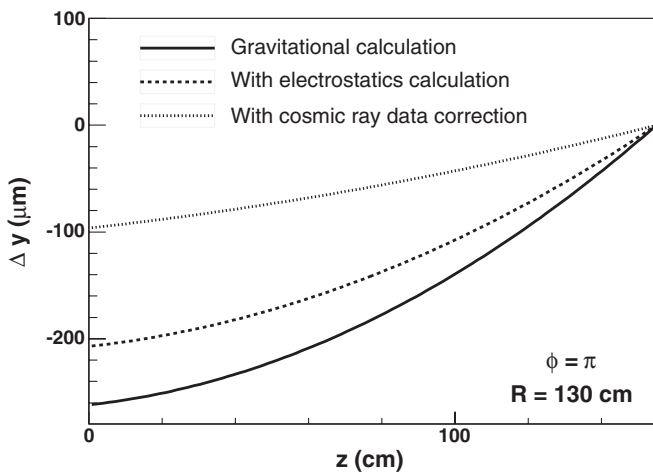

FIG. 19. The net wire shift in  $y$  as a function of  $z$  from gravitational sag only (solid line), including electrostatic effects (dashed line), and including data-based corrections from Eq. (22) (dotted line). The shift is shown at  $\phi = \pi$  and  $R = 130$  cm.

The cell- and wire-based corrections are implemented for the track-finding and fitting stage, and reduce the measured hit resolution for high-momentum muons from  $\approx 180 \mu\text{m}$  to  $\approx 140 \mu\text{m}$ . Final track-based corrections are applied to the measured track curvature, which is inversely related to the transverse momentum [Eq. (21)]. Expanding the measured curvature  $c$  as a function of the true curvature  $c_t$  in a Taylor series around zero,

$$c = \epsilon_1 + (1 + \epsilon_2)c_t + \epsilon_3c_t^2 + \epsilon_4c_t^3 + \dots, \quad (23)$$

the terms even in  $c_t$  cause biases in positive tracks relative to negative tracks, which tend to cancel when the two are averaged. The term linear in  $c_t$  scales the true curvature and is determined by the momentum calibration. The  $\epsilon_4c_t^3$  term is the first to directly affect mass measurements and is suppressed by the  $c_t^3$  factor at low curvature (high momentum).

Corrections for high-momentum tracks from  $W$  and  $Z$  decay particles are determined using the difference in  $E/p$

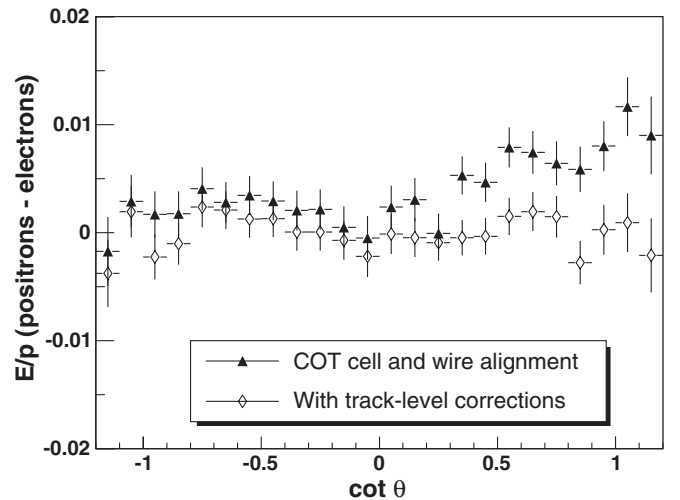

FIG. 20. The difference between  $e^+$  and  $e^- E/p$  as a function of  $\cot\theta$  (top) and  $\phi$  (bottom) before (solid triangles) and after (open diamonds) track-level corrections.

for  $e^+$  and  $e^-$  from  $W$  decays, which should be zero in the absence of misalignments. This difference can be used to constrain  $\epsilon_1$ , the first term in the Taylor expansion. Figure 20 shows the differences in  $E/p$  as functions of  $\cot\theta$  and  $\phi$ , before and after corrections of the following form:

$$\begin{aligned} \delta c = & a_0 + a_1 \cot\theta + a_2 \cot^2\theta + b_1 \sin(\phi + 0.1) \\ & + b_3 \sin(3\phi + 0.5). \end{aligned} \quad (24)$$

The terms can be interpreted as arising from the following physical effects: a relative rotation of the outer edge to the inner edge of each end plate ( $a_0$ ), a relative rotation of the east and west end plates ( $a_1 \cot\theta$ ), and a mismeasurement of the beam position [ $b_1 \sin(\phi + 0.1)$ ]. The measured values of the parameters  $a_0$ ,  $a_1$ ,  $a_2$ ,  $b_1$ , and  $b_3$ , are shown in Table III.

Varying  $a_1$  by  $\pm 3\sigma$  in pseudoexperiments and assuming linear variation of the momentum scale with  $a_1$ , we find the  $a_1$  uncertainty results in a relative momentum scale uncertainty of  $\pm 0.07 \times 10^{-3}$  for  $W$  and  $Z$  boson measurements. The other parameter uncertainties, as well as residual higher-order terms, have a negligible impact on the momentum scale for the  $m_W$  measurement.

## B. $J/\psi \rightarrow \mu\mu$ calibration

With a measured  $\sigma$  times branching ratio (BR) of  $16.3^{+1.4}_{-1.3}$  nb [28],  $J/\psi$  mesons are the Tevatron's most prolific source of resonant decays to muon pairs. In addition to its high statistics, the  $J/\psi$ 's precisely known mass ( $m_{J/\psi} = 3096.88 \pm 0.04$  MeV [59]) and narrow width ( $\Gamma_{J/\psi} = 0.0934 \pm 0.0021$  MeV [42]) make it a key component of the track momentum calibration. We perform measurements of the  $J/\psi$  mass as a function of mean inverse muon  $p_T$  to determine a momentum scale correction and extrapolate to the high- $p_T$  region relevant for  $W$  and  $Z$  boson decays.

### 1. Data sample

The  $J/\psi$  data sample is collected with a level 1 trigger requiring one  $p_T > 1.5$  GeV XFT track with a matching CMU track segment, and a second  $p_T > 1.5(2)$  GeV XFT

TABLE III. The parameters used to correct the track curvature of electrons and muons from  $W$  and  $Z$  boson decays. The values and statistical uncertainties are determined from fits to the  $E/p$  difference between positrons and electrons.

Parameter	Value ( $\times 10^{-7}$ cm $^{-1}$ )
$a_0$	$-0.66 \pm 0.17$
$a_1$	$-1.6 \pm 0.3$
$a_2$	$-2.1 \pm 0.5$
$b_1$	$-2.1 \pm 0.2$
$b_3$	$5.7 \pm 1.7$

track with a matching CMU (CMX) segment. At level 3, the two corresponding COT tracks must have opposite charge and consistent  $z$  vertex positions ( $|\Delta z_0| < 5$  cm), and must form an invariant mass between 2.7 and 4 GeV. The resolution on the invariant mass measurement degrades at high track momentum, so to avoid trigger bias the mass range is extended to  $2 \text{ GeV} < m_{\mu\mu} < 5 \text{ GeV}$  when the  $p_T$  of the muon pair  $p_T^{\mu\mu}$  is greater than 9 GeV.

Candidate events are selected offline by requiring two COT tracks, each with  $p_T > 2$  GeV,  $|d_0| < 0.3$  cm, and  $\geq 7$  hits on each of the eight superlayers. The tracks must originate from a common vertex ( $|\Delta z_0| < 3$  cm) and form an invariant mass in the range (2.95, 3.21) GeV.

A significant fraction ( $\approx 20\%$ ) of the  $J/\psi$  mesons in our data sample result from decays of  $B$  hadrons, which have an average proper decay length of  $\approx 0.5$  mm. The muons from the  $J/\psi$  decay can thus originate outside the beam radius. Therefore, no beam constraint is applied in the COT track fit of muon candidates from  $J/\psi$  decays.

The total sample consists of 606 701  $J/\psi$  candidates in  $(194 \pm 11) \text{ pb}^{-1}$  of integrated luminosity.

## 2. Monte Carlo generation

We use PYTHIA [60] to generate  $J/\psi \rightarrow \mu\mu$  events, from which templates are constructed to fit the data for the momentum scale. The shape of the  $m_{\mu\mu}$  distribution from  $J/\psi$  decays is dominated by the  $p_T$ -dependent detector resolution. We therefore model the  $p_T^{J/\psi}$  distribution as well as the  $p_T$  and relative  $p_T$  of the muons in a  $J/\psi$  decay. To obtain an adequate model, we empirically tune the generated  $J/\psi$  kinematics to describe the relevant data distributions for the  $J/\psi$  mass fits.

To tune the  $p_T^{J/\psi}$  distribution, we boost the  $J/\psi$  momentum by changing its rapidity ( $y_{J/\psi}$ ) along its direction of motion  $\hat{p}_{J/\psi}$ . In 50% of the generated events we multiply  $y_{J/\psi}$  by 1.215, and in the other 50% we multiply it by 1.535. The decay angle  $\theta^*$  in the  $J/\psi$  rest frame relative to  $\hat{p}_{J/\psi}$  is tuned by multiplying  $\cot\theta^*$  by 1.3. After tuning, the simulation matches the relevant background-corrected data distributions, as shown in Fig. 21.

The PYTHIA event generator does not include energy loss due to final-state photon radiation from the muons in  $J/\psi$  decays. To simulate this effect, we scale each muon's momentum by a factor  $x$  determined from the following leading-log probability distribution for soft photon radiation [60,61]:

$$f(x) = \beta(1-x)^{\beta-1}, \quad (25)$$

with

$$\beta = \frac{\alpha_{\text{EM}}}{\pi} [\ln(Q^2/m_\mu^2) - 1] \quad (26)$$

and  $Q^2 = m_{J/\psi}^2$ .

FIG. 21. The  $J/\psi \rightarrow \mu\mu$  data (circles) and tuned simulation (histogram) distributions of  $p_T^{\mu\mu}$  (top) and  $\sum q/p_T^\mu$  (bottom). The  $\sum q/p_T^\mu$  is equal to the sum of the track curvatures of muons from a  $J/\psi$  decay, divided by  $2.11593 \times 10^{-3}$ .

### 3. Momentum scale measurement

The momentum scale is calibrated using  $J/\psi$  decays by fitting the dimuon mass as a function of mean inverse  $p_T$  of the two muons, and then extrapolating to high  $p_T$  ( $\langle p_T^{-1} \rangle \approx 0 \text{ GeV}^{-1}$ ). This procedure results in a track momentum calibration accuracy of 0.025%.

The momentum scale calibration requires an accurate modeling of the muon ionization energy loss in the tracker. Each muon passing through the silicon and COT detectors loses on average 9 MeV at normal incidence. The combined effect on the reconstructed  $m_{\mu\mu}$  is about 0.6% of  $m_{J/\psi}$ , a factor of  $\approx 20$  larger than our total uncertainty. Since the ionization energy loss  $E_I$  varies only logarithmically with  $p_T$  (Sec. III B 1), the relative effect on the reconstructed mass is

$$\frac{\Delta m}{m} = \frac{E_I^{\mu^+}}{2p_T^{\mu^+}} + \frac{E_I^{\mu^-}}{2p_T^{\mu^-}} \approx E_I \langle p_T^{-1} \rangle. \quad (27)$$

Thus, in a linear fit of  $\Delta m/m$  as a function of mean inverse  $p_T$ , a nonzero slope approximately corresponds to  $E_I$ . Since we model the ionization energy loss based on the known detector material, this slope should be zero. We however find that we need to scale down the ionization energy loss from the detector parametrization (Sec. III B 1)

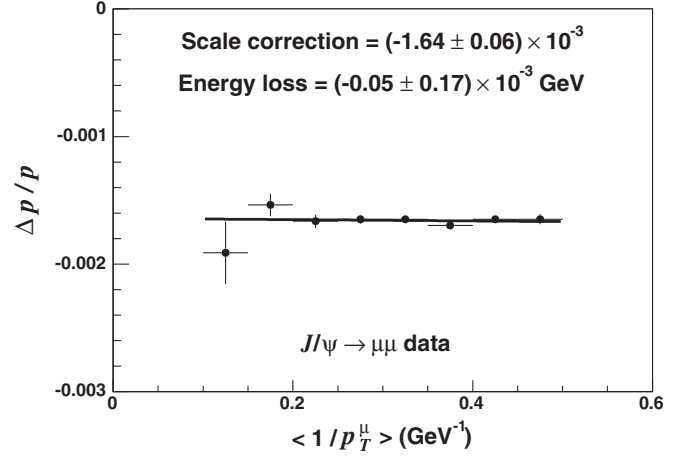

FIG. 22. The fractional momentum correction for data as a function of the mean inverse momentum of the muons from  $J/\psi$  decays. In a linear fit, the intercept corresponds to the scale correction relevant for  $W$  and  $Z$  boson decays, and the slope corresponds to the remaining unmodeled ionization energy loss after material tuning. The uncertainties are statistical only.

by 6% to achieve a zero slope. We show the result of this tuning in Fig. 22, replacing  $\Delta m/m$  on the y axis with the relative momentum correction  $\Delta p/p$  to be applied to the data in order to measure  $m_{J/\psi} = 3096.88 \text{ MeV}$ . The tuning is based on a  $\langle p_T^{-1} \rangle$  region of  $(0.1, 0.5) \text{ GeV}^{-1}$ , divided into eight bins. We find a scale correction of  $\Delta p/p = [-1.64 \pm 0.06(\text{stat})] \times 10^{-3}$  from a linear fit to  $\Delta p/p$  as a function of  $\langle p_T^{-1} \rangle$ .

Each  $\Delta p/p$  value in Fig. 22 is extracted via a binned likelihood fit to the  $m_{\mu\mu}$  distribution for each  $\langle p_T^{-1} \rangle$  bin. Since the mass resolution varies significantly with  $\langle p_T^{-1} \rangle$ , the fit ranges are adjusted from  $3.08 \pm 0.13 \text{ GeV}$  for  $\langle p_T^{-1} \rangle = (0.1, 0.15) \text{ GeV}^{-1}$  to  $3.08 \pm 0.08 \text{ GeV}$  for  $\langle p_T^{-1} \rangle = (0.45, 0.5) \text{ GeV}^{-1}$ . The background is modeled as a linear function of  $m_{\mu\mu}$ , with normalization and slope determined from upper and lower sideband regions whose combined width is equal to that of the mass fit window. The results of the fits in the  $\langle p_T^{-1} \rangle = (0.15, 0.2) \text{ GeV}^{-1}$  and  $\langle p_T^{-1} \rangle = (0.25, 0.3) \text{ GeV}^{-1}$  ranges are shown in Fig. 23.

The  $J/\psi$  momentum calibration includes corrections to the curvature  $c$  derived from the measured dimuon mass as a function of  $\Delta \cot\theta$  between the positive and negative muons from the  $J/\psi$  decay. Biases linear in  $\Delta \cot\theta$  are removed with a curvature correction linear in  $\cot\theta$ :

$$\delta c = [(-7 \pm 1) \times 10^{-7} \text{ cm}^{-1}] \cot\theta, \quad (28)$$

where the uncertainty is statistical only. Biases quadratic in  $\Delta \cot\theta$  are removed with the following correction to the absolute length scale of the COT along the  $z$  axis (statistical uncertainty only):

$$\delta \cot\theta = [(-3.75 \pm 1.00) \times 10^{-4}] \cot\theta. \quad (29)$$

FIG. 23. The  $m_{\mu\mu}$  fits (histograms) to data (circles) with  $\langle p_T^{-1} \rangle = (0.15, 0.2) \text{ GeV}^{-1}$  (top) and  $\langle p_T^{-1} \rangle = (0.25, 0.3) \text{ GeV}^{-1}$  (bottom). The best fits to the  $m_{\mu\mu} = (3.08 \pm 0.12) \text{ GeV}$  (top) and  $m_{\mu\mu} = (3.08 \pm 0.11) \text{ GeV}$  (bottom) regions correspond to momentum scale corrections of  $(-1.54 \pm 0.09) \times 10^{-3}$  (top) and  $(-1.65 \pm 0.04) \times 10^{-3}$  (bottom). The arrows indicate the fit regions and the uncertainties are statistical only. The fit  $\chi^2$  can be improved by adjusting the final-state radiation model, and this effect is incorporated into the systematic uncertainty (Sec. VB 4).

The  $\cot\theta$ -dependent correction to the curvature [Eq. (28)] is larger than the correction derived from  $E/p$  in  $W \rightarrow e\nu$  data ( $a_1$  in Table III). Muons from  $J/\psi$  decay have a broader curvature range and thus a greater dependence on misalignments affecting higher-order terms in curvature. Since we derive a curvature correction averaged over all of the terms in Eq. (23), the  $J/\psi$  correction can be larger than the correction for electrons and muons from  $W$  and  $Z$  boson decays.

#### 4. Momentum scale uncertainties

Systematic uncertainties on the momentum scale correction extracted from  $J/\psi \rightarrow \mu\mu$  decays (Table IV) are dominated by the incompleteness of the QED and energy-loss models. At low muon  $p_T$  (high  $\langle p_T^{-1} \rangle$ ), the mass fits become increasingly sensitive to QED and energy-loss modeling because of the better mass resolution and higher statistics. Since we only model the mean ionization energy loss, our modeling of the mass region below the peak is imperfect. Additionally, our neglect of higher-order QED corrections affects the modeling of this region. We study possible bias from our incomplete model by changing the  $Q^2$  value in the photon radiation probability function [Eq. (25)] such that the  $\chi^2$  of the inclusive  $m_{\mu\mu}$  fit is minimized. We find that this change affects  $\Delta p/p$  by  $0.2 \times 10^{-3}$ .

Any residual miscalibration of the magnetic field in track reconstruction can cause a variation of the measured  $J/\psi$  mass with the average  $\cot\theta$  of the muons. We study the  $\cot\theta$  dependence of  $\Delta p/p$  using  $J/\psi$  decays where both muons are measured in the same  $\cot\theta$  region ( $|\Delta \cot\theta(\mu\mu)| < 0.1$ ). We find that if we correct for the observed variation with  $\cot\theta$ , the extracted  $\Delta p/p$  changes by  $0.1 \times 10^{-3}$ .

The uncertainty on the material correction propagates to a momentum scale uncertainty of  $0.06 \times 10^{-3}$  when extrapolated to high momentum, as shown in Fig. 22. An additional statistical uncertainty of  $0.01 \times 10^{-3}$  on the

TABLE IV. Uncertainties on the momentum scale correction derived from the  $J/\psi$  and  $\Upsilon$  mass measurements.

Source	$J/\psi$ ( $\times 10^{-3}$ )	$\Upsilon$ ( $\times 10^{-3}$ )	Common ( $\times 10^{-3}$ )
QED and energy-loss model	0.20	0.13	0.13
Magnetic field nonuniformities	0.10	0.12	0.10
Beam-constraint bias		0.06	0
Ionizing material scale	0.06	0.03	0.03
COT alignment corrections	0.05	0.03	0.03
Fit range	0.05	0.02	0.02
Trigger efficiency	0.04	0.02	0.02
Resolution model	0.03	0.03	0.03
Background model	0.03	0.02	0.02
World-average mass value	0.01	0.03	0
Statistical	0.01	0.06	0
Total	0.25	0.21	0.17

scale is determined by fixing the material correction and fitting for the scale.

The statistical uncertainties on the  $J/\psi$  alignment corrections [Eqs. (28) and (29)] have a  $0.05 \times 10^{-3}$  effect on  $\Delta p/p$ . We test our model of the  $m_{\mu\mu}$  line shape by changing the fit range by  $\pm 20\%$ , and find a  $\pm 0.05 \times 10^{-3}$  change in  $\Delta p/p$ .

We apply the same  $p_T$  thresholds offline as in the trigger for muons with CMU segments. Since we do not model a  $p_T$ -dependent trigger efficiency, any inefficiency could cause a bias in the reconstructed  $m_{\mu\mu}$ . We investigate this possibility by varying the offline  $p_T$  thresholds by  $\pm 5\%$ , and find a  $\Delta p/p$  variation of  $\pm 0.04 \times 10^{-3}$ .

The quality of the fit is highly sensitive to the hit-resolution model, but the momentum scale correction is not. Changing the simulated COT hit resolution by  $\pm 10 \mu\text{m}$ , which corresponds to a  $>10\sigma$  statistical variation, results in a  $\pm 0.03 \times 10^{-3}$  change in  $\Delta p/p$ . We include this in our systematic uncertainty estimate.

A  $\pm 0.03 \times 10^{-3}$  uncertainty on  $\Delta p/p$  from the background model is determined by changing its linear dependence on  $m_{\mu\mu}$  to a constant. Finally, the world-average  $J/\psi$  mass value used in this measurement contributes  $\pm 0.01 \times 10^{-3}$  to the uncertainty on  $\Delta p/p$ .

The final momentum scale correction derived from  $J/\psi$  data is

$$\Delta p/p = (-1.64 \pm 0.25) \times 10^{-3}. \quad (30)$$

### C. $Y \rightarrow \mu\mu$ calibration

The  $b\bar{b}$  resonance  $Y$  provides a complementary momentum scale calibration tool to the  $J/\psi$ . Its precisely measured mass  $m_Y = (9460.30 \pm 0.26) \text{ MeV}$  [42] is 3 times larger than that of the  $J/\psi$ , so an  $Y$  momentum scale calibration is less sensitive to the material and energy-loss model than that of the  $J/\psi$ . Because the  $b\bar{b}$  resonances are the highest mass mesons, long-lived hadrons do not decay to the  $Y$  and the muons from  $Y$  decay effectively originate from the collision point. We improve the accuracy of the muon measurements by constraining their tracks to the beam position, which is the same procedure applied to the  $W$  and  $Z$  decay lepton tracks.

The  $Y$  data sample is based on the same level 1 trigger as the  $J/\psi$  sample (Sec. V B 1). The level 3 requirements are one reconstructed track with  $p_T > 4 \text{ GeV}$  and matching CMU and CMP track segments (CMUP); a second track with opposite charge to the first,  $p_T > 3 \text{ GeV}$ , and a matching CMU or CMX track segment; and a reconstructed mass of the two tracks between 8 and 12 GeV. Offline, the  $p_T$  thresholds are increased to 4.2 (3.2) GeV for the track with a CMUP (CMU or CMX) track segment, and each track must have  $|d_0| < 0.3 \text{ cm}$  and at least 5 hits in at least 3 axial and 3 stereo superlayers. The two tracks are required to have a common vertex ( $|\Delta z_0| < 3 \text{ cm}$ ).

We model  $Y$  production and decay using PYTHIA [60], to which we apply the same tuning procedure as for  $J/\psi$  generation. The data  $p_T^Y$  distribution is matched in simulation by boosting the rapidity of each decay muon by  $0.07y_Y$  along  $\hat{p}_Y$ , where  $y_Y$  is the  $Y$  rapidity. Radiation of photons from the final-state muons is simulated using the probability distribution of Eqs. (25) and (26). The  $p_T^{\mu\mu}$  and  $p_T^\mu$  distributions are shown in Fig. 24, after subtracting background from the data.

We test any possible beam-constraint bias by separately reconstructing charged muon tracks from  $Y$  decays with and without incorporating the beam constraint. For the sample with beam-constrained tracks we fit for  $m_Y$  in the region  $9.28 \text{ GeV} < m_{\mu\mu} < 9.58 \text{ GeV}$ , while for the sample with non-beam-constrained tracks we fit the region  $9.25 \text{ GeV} < m_{\mu\mu} < 9.61 \text{ GeV}$ . In  $(191 \pm 11) \text{ pb}^{-1}$  of integrated luminosity, we have 34 618  $Y$  candidates with beam-constrained tracks and 35 622 candidates with non-beam-constrained tracks. The two momentum scale measurements are shown in Fig. 25 and are consistent at the  $2\sigma$  level when correlations are taken into account. We define the  $Y$  result to be the mean of the two values, and take half their difference ( $\Delta p/p = 0.06 \times 10^{-3}$ ) as a systematic uncertainty on the measurement.

The remaining systematic uncertainties on the momentum scale measurement with  $Y$  decays are common to

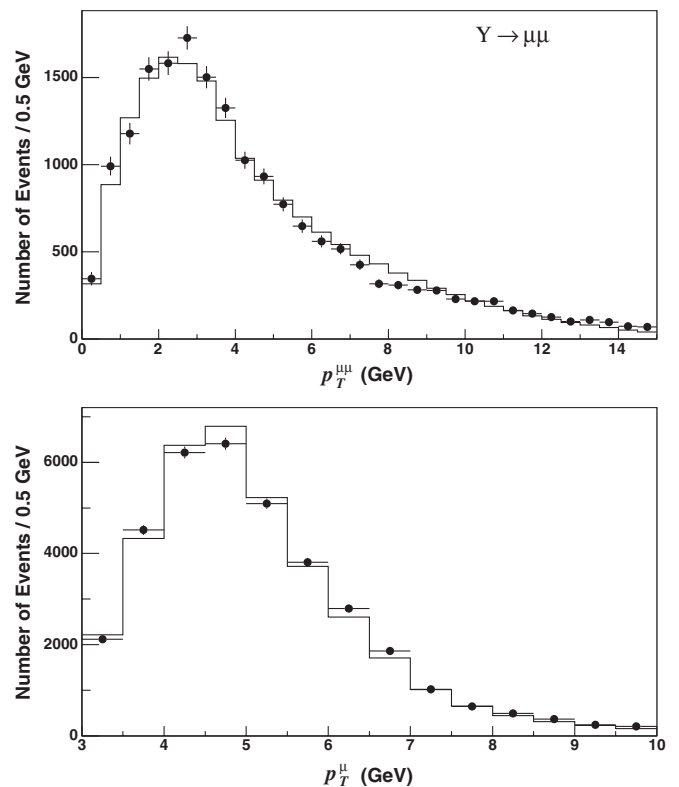

FIG. 24. The  $p_T^{\mu\mu}$  (top) and  $p_T^\mu$  (bottom) distributions from  $Y \rightarrow \mu\mu$  decays for the data (circles) and simulation (histogram).

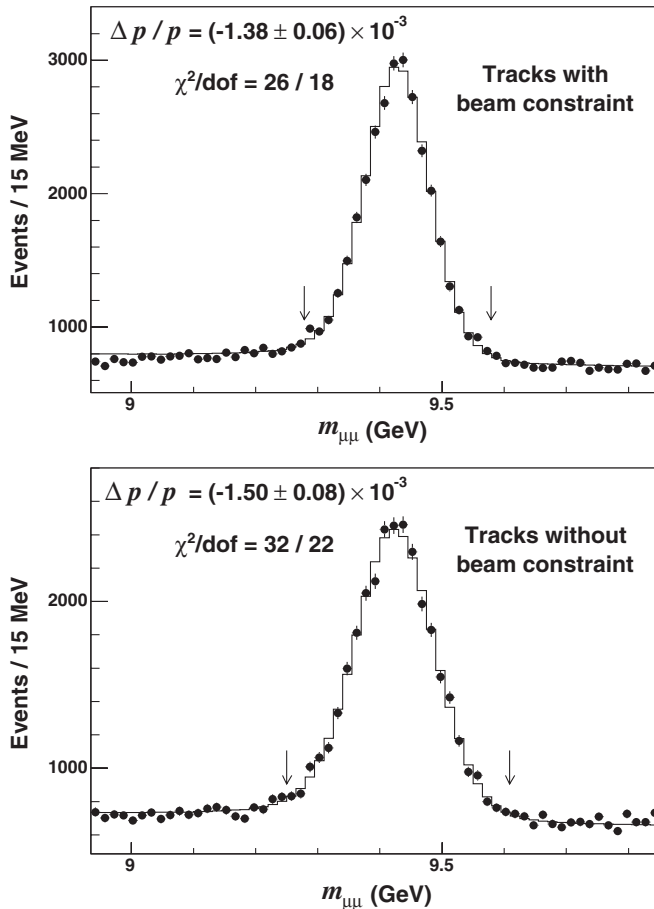

FIG. 25. The momentum scale correction  $\Delta p/p$  derived from binned likelihood fits to the  $m_{\mu\mu}$  data distribution (circles) in the region dominated by  $\Upsilon \rightarrow \mu\mu$  decays. The small difference between fits using tracks with (top) and without (bottom) a beam constraint is incorporated into the systematic uncertainty. The arrows indicate the fit region and the uncertainties are statistical only.

those of the measurement with  $J/\psi$  decays. We use the same procedures as with the  $J/\psi$  calibration to estimate the sizes of the uncertainties, with one exception. Since the  $\Upsilon$  sample has  $<10\%$  of the statistics of the  $J/\psi$  sample, the QED and energy-loss model cannot be tested with the  $\chi^2$  of the  $\Upsilon \rightarrow \mu\mu$  mass fit. Instead, we change  $Q$  in the photon radiation probability function by the amount estimated for the  $J/\psi$  systematic uncertainty (Sec. VB 4). We find that this variation affects  $\Delta p/p$  by  $\pm 0.13 \times 10^{-3}$  in the  $\Upsilon$  calibration.

The final result of the  $\Upsilon$  calibration is

$$\Delta p/p = (-1.44 \pm 0.21) \times 10^{-3}. \quad (31)$$

We have verified that this result has no time dependence, at the level of the statistical precision of  $\pm 0.13 \times 10^{-3}$ . When combined with the momentum scale correction from the  $J/\psi$  calibration, we obtain

$$\Delta p/p = (-1.50 \pm 0.19) \times 10^{-3}. \quad (32)$$

#### D. $Z \rightarrow \mu\mu$ calibration

Given the precise momentum scale calibration from the  $J/\psi$  and  $\Upsilon$  decays, we measure the  $Z$  boson mass and compare it to the world-average value  $m_Z = (91\,187.6 \pm 2.1)$  MeV [11,42]. We then use the world-average  $m_Z$  to derive an additional  $\Delta p/p$  calibration and combine it with that of the  $J/\psi$  and  $\Upsilon$  decays.

The systematic uncertainties of the  $m_Z$  measurement are correlated with those of the  $m_W$  measurement, so a momentum scale calibration with  $Z$  bosons can reduce systematic uncertainties on the  $m_W$  measurement. However, the statistical uncertainty from the  $Z \rightarrow \mu\mu$  sample is significantly larger than the calibration uncertainty from  $J/\psi$  and  $\Upsilon$  decays. Thus, the main purpose of the  $m_Z$  measurement is to confirm the momentum scale calibration and test our systematic uncertainty estimates.

The  $Z$  boson data sample is selected using the same single-muon trigger and offline muon selection as for the  $W$  boson sample (Secs. III A 4 and IV A), with the exception that we remove the requirement of a track segment in a muon detector for one of the muons from the  $Z$  boson decay. Removing this requirement significantly increases detector acceptance while negligibly affecting background.  $Z$  boson candidates are defined by  $66 \text{ GeV} < m_{\mu\mu} < 116 \text{ GeV}$ ,  $p_T^{\mu\mu} < 30 \text{ GeV}$ ,  $|\Delta t_0(\mu, \mu)| < 3 \text{ ns}$ , and oppositely charged muons. A muon track's  $t_0$  is defined as the time between the  $p\bar{p}$  bunch crossing and the muon's production, and should be  $(0 \pm 1)$  ns for  $Z \rightarrow \mu\mu$  production and decay. The track  $t_0$  is measured using the time information from the track hits in the COT by incorporating  $t_0$  into the helical fit. The  $|\Delta t_0| < 3 \text{ ns}$  requirement effectively removes cosmic-ray muons passing through the detector. An additional cosmic-ray identification algorithm [58] reduces this background to a negligible size. After applying all selection criteria, the  $Z \rightarrow \mu\mu$  sample contains 4960 events in  $(191 \pm 11) \text{ pb}^{-1}$  of integrated luminosity.

We model  $Z$  boson production and decay using the RESBOS [62] event generator and a next-to-leading-order QED calculation of photon radiation from the final-state muons [63] (Sec. IX). For  $m_{\mu\mu}$  near the  $Z$  boson resonance, the photon propagator and  $Z/\gamma^*$  interference make small contributions to the shape of the  $m_{\mu\mu}$  distribution. We separately simulate these components and include them as fixed “background” to the  $Z$  line shape. We measure  $m_Z$  using a binned likelihood template fit to the data in the range  $83 \text{ GeV} < m_{\mu\mu} < 99 \text{ GeV}$  (Fig. 26). Our measurement of  $m_Z = [91.184 \pm 0.043(\text{stat})] \text{ GeV}$  is in good agreement with the world-average value of  $m_Z = (91.188 \pm 0.002) \text{ GeV}$  [11,42].

Systematic uncertainties on  $m_Z$  are due to the momentum scale calibration (17 MeV), alignment correction un-

FIG. 26. The  $m_Z$  fit to data (circles) in the  $83 \text{ GeV} < m_{\mu\mu} < 99 \text{ GeV}$  region (denoted by arrows). The uncertainty is statistical only.

certainties (7 MeV), and incomplete modeling of higher-order QED corrections (14 MeV). The combined statistical and systematic uncertainty is 49 MeV.

Given the precise world-average measurement of  $m_Z$ , we use the  $Z$  boson resonance as an additional calibration input to  $\Delta p/p$ . We find that adding the  $m_Z$  information reduces  $\Delta p/p$  and its uncertainty by less than  $0.01 \times 10^{-3}$  each.

Incorporating the alignment uncertainty (Sec. VA) into  $\Delta p/p$  from Eq. (32) gives the momentum scale correction applicable to the  $W$  boson sample:

$$\Delta p/p = (-1.50 \pm 0.21) \times 10^{-3}. \quad (33)$$

The corresponding uncertainty on the  $m_W$  fits in the muon channel is 17 MeV.

## VI. ELECTRON ENERGY MEASUREMENT

An electron's energy is measured from its shower in the electromagnetic calorimeter. As part of the data reconstruction, we apply an approximate calibration by scaling the measured energy such that a Gaussian fit to the reconstructed dielectron mass in a region dominated by  $Z$  decays (86–98 GeV) gives a mean of 91 GeV. This is slightly below the world-average  $m_Z$  because the Gaussian fit is biased by the energy lost to final-state photon radiation (Sec. IX D). This initial data calibration is accurate to  $\approx 0.15\%$ .

To model the data, the simulated calorimeter energy is scaled to match the measured  $E/p$  distribution of electrons in  $W \rightarrow e\nu$  events. A calibrated data measurement would result in an  $E/p$  of unity for electrons that do not radiate before entering the calorimeter, and deposit all of their energy in the EM calorimeter. We verify that the  $E/p$  calibration is unbiased by using it to measure  $m_Z$  in dielectron events. Given the consistency of the measured  $m_Z$  with the world-average value, we incorporate the  $m_Z$  fit into the

calibration. The final calibration has an accuracy of 0.037%.

### A. $E/p$ calibration

We transfer the precise tracker calibration to the calorimeter using the ratio of electron calorimeter energy to track momentum,  $E/p$ . The material from the beam pipe to the inner COT wall causes bremsstrahlung that affects the measured position of the  $E/p$  peak, and this material is scaled in the simulation such that the simulation matches the data in the high- $E/p$  region. The nonlinearity of the energy scale is modeled by applying a correction to the simulation scale as a function of the incident particle  $p_T$  [Eq. (17)]. Finally, corrections are applied to the data to improve uniformity in response as a function of detector tower and time. After the complete set of corrections and simulation calibrations, the simulation energy scale  $S_E$  is determined from a maximum likelihood template fit to the  $E/p$  peak region.

The shape of the  $E/p$  distribution has a strong dependence on the material upstream of the COT. Bremsstrahlung in this material reduces the measured electron momentum in the tracker while leaving the measured calorimeter energy unchanged, since photons are radiated collinearly with the electron and deposit their energy in the same calorimeter tower as the electron. Thus, the effect of bremsstrahlung is to shift the measured  $E/p$  to values  $>1$ . If the material is not well modeled, the energy scale calibration will be biased to compensate for the mismodeling.

A detailed accounting of the silicon and COT tracker material was performed at installation. In the early data-taking period, the radial distribution of photon conversions was compared between data and a full GEANT simulation. The amount of copper cable was increased by a few percent of  $X_0$  in the GEANT simulation to correct observed discrepancies, and the three-dimensional lookup table of material properties (Sec. III B 1) was produced from this corrected GEANT simulation.

For a final material tuning, we compare our parametrized simulation to the data in the high- $E/p$  region ( $1.19 \leq E/p < 1.85$ ) of electrons from  $W$  boson decays. Using the region  $0.85 \leq E/p < 1.19$  for normalization, we perform a maximum likelihood fit to the  $1.19 \leq E/p < 1.85$  region in two bins (Fig. 27) and measure a multiplicative correction factor  $S_{\text{mat}} = 1.004 \pm 0.009(\text{stat})$  to the number of radiation lengths [64]. As a further consistency check of the material lookup table, we determine  $S_{\text{mat}}$  as a function of tower  $|\eta|$ , and find no statistically significant dependence on  $|\eta|$ .

Our simulation of electron interactions in the tracker and calorimeter accounts for most of the energy dependence of the energy scale. Any residual nonlinearity is incorporated as a per-particle correction in the simulation (Sec. III B 2). To measure this nonlinearity, we fit the  $E/p$  peak region

FIG. 27. The maximum likelihood fit (histogram) for the multiplicative correction factor to the number of tracker radiation lengths using the high- $E/p$  region ( $1.19 \leq E/p < 1.85$ ) in  $W \rightarrow e\nu$  data (circles).

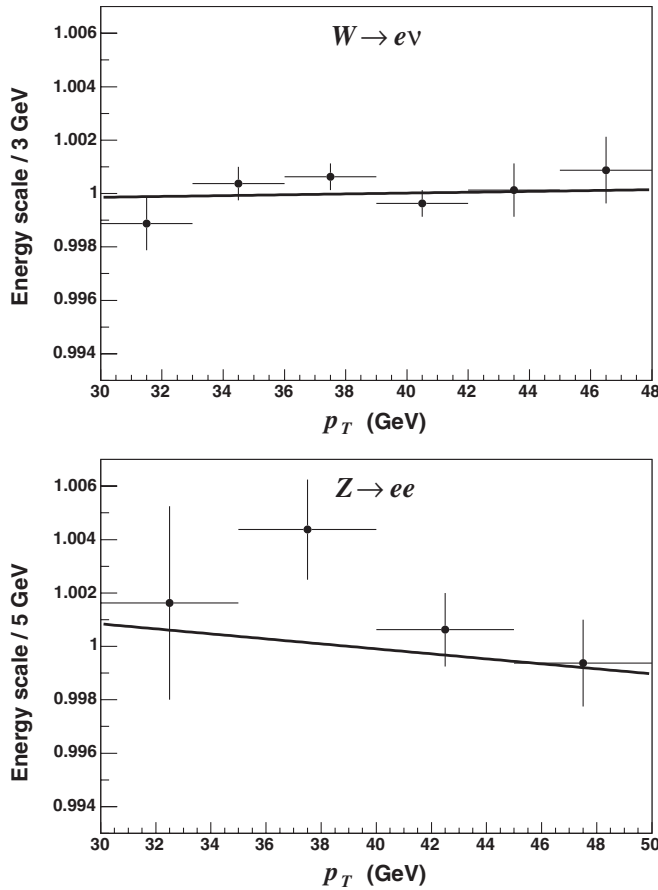

FIG. 28. The energy scale as a function of measured electron calorimeter  $p_T$  for  $W$  (top) and  $Z$  (bottom) boson decays. The fast simulation incorporates a per-particle nonlinear response correction [Eq. (17)]. Combining the individual linear fits to  $\xi$ , shown in the figure, results in no energy dependence of the energy scale.

( $0.93 \leq E/p < 1.11$ ) for the energy scale in bins of measured calorimeter  $p_T$  of the electrons (Fig. 28). The resulting energy scale measurements are fit as a linear function of  $p_T$ , fixing the scale to 1 at the  $W$  boson sample's  $\langle p_T^e \rangle = 39$  GeV. The error-weighted average,  $\xi = [6 \pm 7(\text{stat})] \times 10^{-5}$ , of the measurements of the nonlinearity parameter from the  $W$  and  $Z$  boson samples is used in Eq. (17). The linear fits in Fig. 28, where the simulation includes this correction, show a constant energy scale [65].

To improve the energy resolution of the data, we apply time-dependent and tower-dependent calibrations derived from low-energy EM clusters. At level 3 the relevant trigger requires calorimeter and track  $p_T$  greater than 8 GeV each, as well as electron identification based on track-calorimeter matching and calorimeter shower shape properties. Offline, candidates are required to have  $\text{Had}/\text{EM} < 0.05$  and  $E + p > 22$  GeV to remove any trigger bias. Using the mean of the  $E/p$  range 0.8–1.25, we apply relative corrections of  $\mathcal{O}(3\%)$  to remove variations as functions of tower and time.

Because of bremsstrahlung radiation in the tracker, the mean  $E/p$  correction has a small bias that depends on the electron path length. Since the path length increases as  $|\eta|$  increases, we perform a final  $|\eta|$ -dependent calibration of the data. Using template fits to the  $E/p$  peak region of the  $W \rightarrow e\nu$  sample in bins of  $|\eta|$ , we derive a relative correction for each bin. This calibration removes  $\approx 1\%$  residual variation in the calorimeter energy response.

With the complete set of corrections applied to the data and simulation, we calibrate the simulation energy scale using  $W \rightarrow e\nu$  events. The fit for  $S_E$  [Eq. (17)] to the  $E/p$  peak region (Fig. 29) has a statistical uncertainty of 0.025%. Including systematic uncertainties due to  $S_{\text{mat}}$  ( $\pm 0.011\%$ ) and the tracker momentum scale ( $\pm 0.021\%$ ), we obtain a total uncertainty of 0.034% on the  $E/p$  calibration of the electron energy scale.

FIG. 29. The energy scale calibration using the peak  $E/p$  region ( $0.93 \leq E/p < 1.11$ , denoted by arrows) in  $W \rightarrow e\nu$  data (circles).

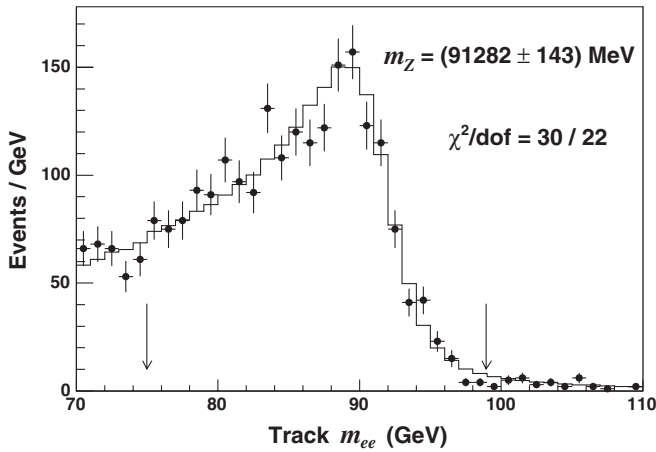

FIG. 30. The  $m_Z$  fit (histogram) to data (circles) in the  $75 \text{ GeV} < m_{ee} < 99 \text{ GeV}$  region (denoted by arrows), using reconstructed track information only. The uncertainty is statistical only.

The  $E/p$  calibration requires an accurate simulation of electron radiation in the tracker. We test the track simulation by measuring  $m_Z$  (Sec. VI B) using electron track information only. The measurement is a binned likelihood fit to the region  $75 \text{ GeV} < m_{ee} < 99 \text{ GeV}$  (Fig. 30), with  $m_Z$  as the fit parameter. Because of the significant radiated energy loss, the test is less precise than the measurement using the calorimeter (Fig. 31). Nevertheless, we obtain good consistency with the world-average  $m_Z$ , verifying that we do not have any significant mismodeling of electron radiation in the tracker.

### B. $Z \rightarrow ee$ calibration

Using the  $E/p$ -based calorimeter energy calibration, we measure the  $Z$  boson mass from its decay to two electrons. After confirming the consistency of the result with the world-average mass, we fix  $m_Z$  to this value and produce

FIG. 31. The  $m_Z$  fit to data (circles) in the  $81 \text{ GeV} < m_{ee} < 101 \text{ GeV}$  region (denoted by arrows). The uncertainty is statistical only.

a combined calibration from the electron  $E/p$ -based method and  $Z \rightarrow ee$  mass measurement.

We select  $Z$  bosons using the same single-electron trigger and offline electron selection as for the  $W$  boson sample (Secs. III A 4 and IV B), and define candidates as oppositely charged electrons with  $66 \text{ GeV} < m_{ee} < 116 \text{ GeV}$  and  $p_T^{ee} < 30 \text{ GeV}$ . The  $Z$  boson sample contains 2919 events in  $(218 \pm 13) \text{ pb}^{-1}$  of data.

The sample includes a small component of multijet and  $W + \text{jet}$  background. From a comparison of the data with like-sign electrons to a prediction of the full GEANT simulation, we estimate the background fraction to be  $\leq 0.5\%$ . Since  $\langle m_{ee} \rangle$  of the background is  $\approx 2 \text{ GeV}$  less than that of the  $Z$  boson sample in the fit region, we estimate any corresponding bias on the measured  $m_Z$  to be  $\leq 10 \text{ MeV}$ .

The model for  $Z$  boson production and decay to electrons is the same as for the muon decay channel (Sec. V D). We use the RESBOS [62] event generator and a next-to-leading-order QED calculation of photon radiation from the final-state electrons [63] (Sec. IX). We include the virtual photon exchange and  $Z/\gamma^*$  interference contributions as fixed “backgrounds” to the  $Z$  boson line shape, and determine  $m_Z$  from a binned likelihood fit to the data in the range  $81 \text{ GeV} < m_{ee} < 101 \text{ GeV}$  (Fig. 31).

Systematic uncertainties on the  $m_Z$  measurement result from the  $E/p$  calibration (29 MeV), calorimeter nonlinearity measurement (23 MeV), and higher-order QED radiation (14 MeV). The measured  $m_Z = [91.190 \pm 0.067(\text{stat})] \text{ GeV}$  is consistent with the world-average value  $m_Z = (91.188 \pm 0.002) \text{ GeV}$  [11,42], given the total uncertainty of 78 MeV on the measurement.

The uncorrelated uncertainties in the combination of the  $m_Z$  and  $E/p$  calibrations are the uncertainty on the nonlinearity parameter  $\xi$ , the statistical uncertainty on the  $m_Z$  measurement (0.073%), and the uncertainty on the  $E/p$  calibration (0.034%). Since the  $m_W$  fit relies predominantly on the shape of the Jacobian edge of the  $m_T$  distribution, the relevant electron transverse energies are in the  $\approx 40\text{--}45 \text{ GeV}$  range. The uncertainty on the energy dependence of the scale from the  $Z$  boson mass is negligible, as the  $\langle p_T^e \rangle$  is about 42 GeV in this sample. The  $E/p$ -based calibration involves an extrapolation from  $\langle p_T^e \rangle = 39 \text{ GeV}$ , so it receives an additional uncertainty contribution of 23 MeV to the  $m_W$  measurement from the nonlinearity parameter  $\xi$ . Combining the two calibrations, we obtain a total electron energy measurement uncertainty of 30 MeV on the  $m_W$  measurement in the electron channel. Of this uncertainty, we take 17 MeV to be 100% correlated with the muon channel through the momentum scale uncertainty.

## VII. RECOIL MEASUREMENT

The recoil  $\vec{u}_T$  (Fig. 5) in a  $W$  boson event results from quark or gluon radiation in the initial state, and from photon radiation in the initial and final states. A quark or

gluon typically fragments into multiple hadrons, which are detected in the calorimeter. Additional energy from the underlying event is also measured in the calorimeter and obscures the recoil measurement. Rather than rely on detailed modeling of the underlying event, we develop an empirical model of the recoil  $\vec{u}_T$  using  $Z$  boson events, where the four-momentum of the  $Z$  boson is measured precisely using its leptonic decays. The model of the recoil  $\vec{u}_T$  measurement is tuned with these decays and applied to  $W$  boson events.

We measure the recoil energy using all calorimeter towers except those with ionization or shower energy from the charged leptons. To reduce potential bias and facilitate our model parametrization, we correct the measured energy in each tower for acceptance variations. In addition, we improve the measurement resolution by correcting for response differences between the central and plug calorimeters.

### A. Data corrections

The data used in this analysis have a sinusoidal azimuthal variation in observed energy per tower that increases with increasing  $|\eta|$ . The variation can result from the relative misalignment between the calorimeter and the tracker, or from the relative offset of about 4 mm between the beam line and the center of the CDF II detector. The misalignment can cause a mismeasurement of the tower angles with respect to the center of the detector, resulting in a mismeasurement of the tower transverse energy. The beam offset results in a variation in calorimeter acceptance as a function of  $\phi$  such that the calorimeter towers closest to the beam line have a larger acceptance, and thus a larger average measured energy per tower.

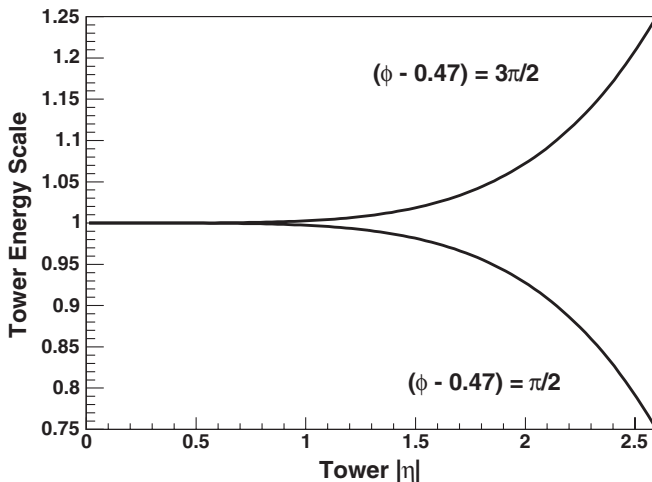

FIG. 32. The maximal energy correction factors applied to each tower as a function of  $|\eta|$ . The decreasing curve corresponds to towers closest to the beam line, and the increasing curve corresponds to towers on the opposite side. The correction factors reduce the  $\phi$  variation in acceptance.

We suppress the observed azimuthal energy variation by applying a threshold on the combined EM and hadronic tower  $p_T$  of 5 GeV for towers with detector  $|\eta| > 2.6$ . The threshold strongly suppresses the forward tower energy variation in  $W$  boson events, while retaining the energy from high- $p_T$  hadronic jets in multijet events. All other towers have EM and hadronic energy thresholds of 20 MeV each.

We reduce the residual azimuthal energy variation by applying a multiplicative correction factor to each measured tower energy according to the following empirical function (Fig. 32):

$$S_{\text{tower}} = 1 - 0.6(0.32|\eta|)^{4.74} \sin(\phi - 0.47). \quad (34)$$

This correction is determined using events collected by a minimum bias trigger, which requires evidence of an inelastic  $p\bar{p}$  collision (Sec. III A 5). We find that this azimuthal recoil calibration reduces the measured uncertainties on our recoil model parameters (Sec. VIII C).

The relative energy scale between the central and forward calorimeters is initially determined from the calibration of high- $p_T$  hadronic jets. The relative response has a significant energy dependence, however, and the initial calibration is not optimized for the low  $p_T$  particles relevant to the  $W$  boson recoil measurement. Using the  $E/p$  distribution of charged pions from minimum bias events, we find that a relative energy scale of  $\approx 12\%$  between central and forward calorimeters is appropriate for particles with  $p_T \lesssim 2$  GeV, the momentum region of a typical recoil particle. To maintain the mean recoil energy scale, we scale the central (forward) calorimeter tower energies up (down) by 5% (7%). This calibration improves the recoil resolution, and thus the statistical precision of the  $m_W$  fits. It also minimizes the sensitivity of the recoil model to differences in phase space sampled by the selected  $W$  and  $Z$  boson decays.

### B. Lepton tower removal

The recoil  $\vec{u}_T$  is measured as the sum of corrected  $\vec{p}_T$  in all calorimeter towers (Sec. VII A), excluding the towers in which the lepton(s) deposit energy. The exclusion of these towers also removes some recoil energy from the measurement, thus causing a bias in  $u_{||}$ . We measure this bias from the data and incorporate it in the simulation.

An electron shower typically distributes energy to two calorimeter towers, but can also contribute to a third tower if the electron is near a tower edge. We remove each tower neighboring the electron's tower, as well as the corner towers closest to the electron's CES position (Fig. 33). A muon near a tower edge can cross two towers, so we remove the two towers in  $\eta$  neighboring the muon's tower (Fig. 34). The tower window definitions are motivated by the presence of excess energy in a given tower above the background energy from the underlying event.

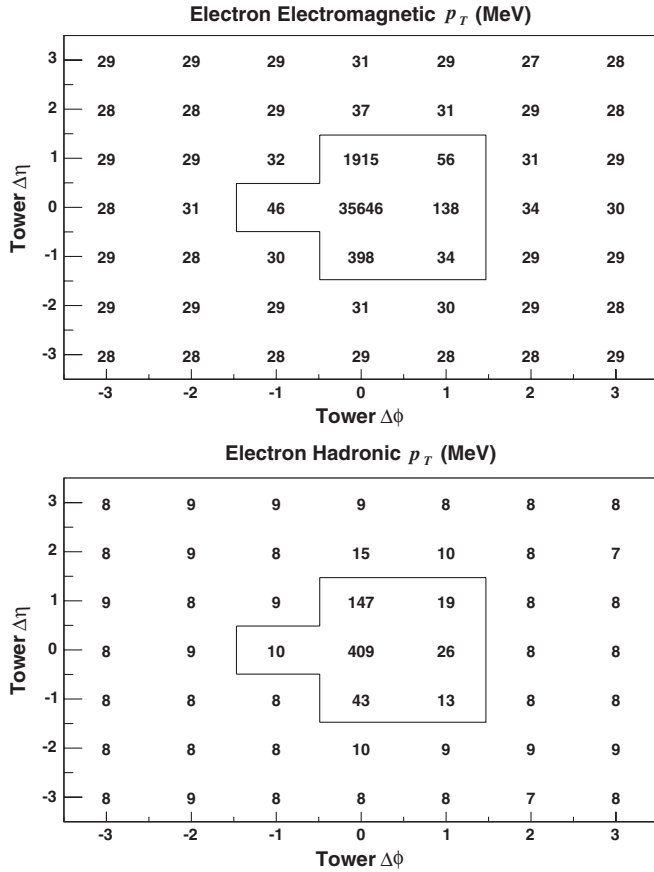

FIG. 33. The average  $p_T$  measured by the electromagnetic (top) and hadronic (bottom) calorimeters in the vicinity of the electron shower in  $W$  boson decays. The differences  $\Delta\phi$  and  $\Delta\eta$  are signed such that positive differences correspond to towers closest to the electron position at shower maximum. The central seven towers inside the box are removed from the recoil measurement. Statistical uncertainties on the values outside the box are  $\mathcal{O}(1 \text{ MeV})$ .

We estimate the recoil energy flow into the excluded towers, denoted by  $\Delta u_{||}$ , using equivalent windows separated in  $\phi$  from the lepton in  $W \rightarrow l\nu$  events. When simulating a  $W$  or  $Z$  boson event, we correct the simulated  $\vec{u}_T$  by a  $\Delta u_{||}$  taken from the measured distribution. The simulated  $\Delta u_{||}$  incorporates its measured dependence on  $u_{||}$  and  $u_{\perp}$ , and lepton  $|\eta|$ . These dependencies are shown for  $W \rightarrow \mu\nu$  events in Fig. 35 and similar functions are defined for electrons. The incorporation of these functions preserves  $\langle \Delta u_{||} \rangle$ , which is 269 MeV for electrons and 112 MeV for muons (with negligible statistical uncertainty).

To estimate the systematic uncertainty associated with modeling the tower removal, we study the variation of  $\Delta u_{||}$  in the data as a function of the  $\phi$  separation from the lepton of the equivalent tower window. We take half the variation as a systematic uncertainty: 8 (5) MeV for removed electron (muon) towers. To confirm our estimate of this uncertainty, we remove an additional window azimuthally

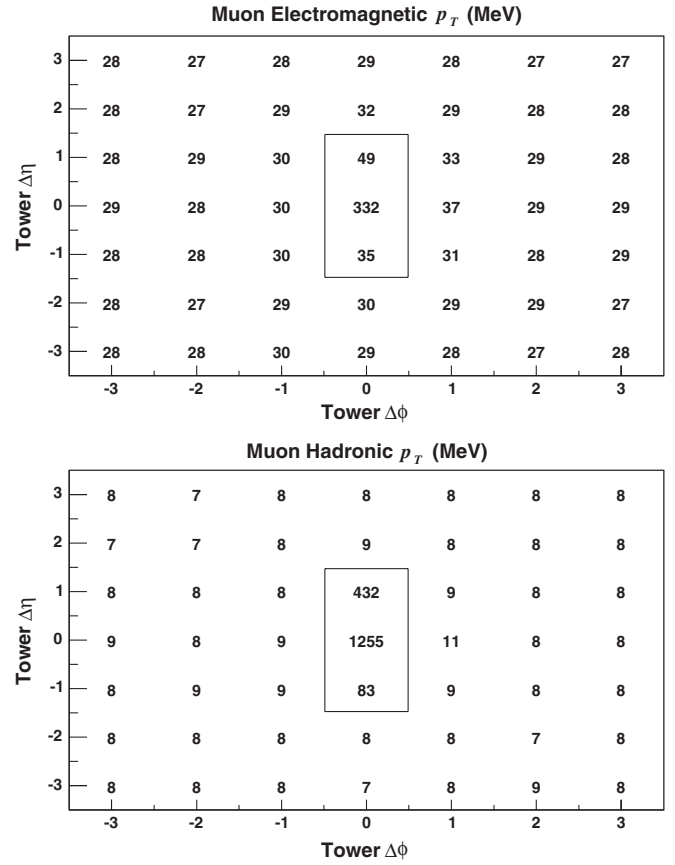

FIG. 34. The average  $p_T$  measured by the electromagnetic (top) and hadronic (bottom) calorimeters in the vicinity of the muon in  $W$  boson decays. The differences  $\Delta\phi$  and  $\Delta\eta$  are signed such that positive differences correspond to towers closest to the muon position at the shower maximum detector. The central three towers inside the box are removed from the recoil measurement. Statistical uncertainties on the values outside the box are  $\mathcal{O}(1 \text{ MeV})$ .

opposite to the lepton ( $\Delta\phi = \pi$ ), incorporate its model into the simulation, and compare the resulting simulation and data  $u_{||}$  distributions. We find the differences to be consistent within our quoted uncertainties.

### C. Recoil model parametrization

The recoil consists of three separate components: radiation in the  $W$  or  $Z$  boson production, radiation from the spectator partons, and energy from additional  $p\bar{p}$  collisions in a given bunch crossing. We use the RESBOS [62] generator to predict the net  $p_T$  distribution of radiation in the  $W$  or  $Z$  boson production, and minimum bias data for the  $p_T$  distribution from spectator partons and additional interactions. The parameters for the detector response to the recoil are measured in  $Z$  boson events.

To facilitate tuning of the recoil model, we define axes such that quark and gluon radiation lies predominantly along one axis, denoted as the “ $\eta$ ” axis (Fig. 36). This axis is chosen to be the angular bisector of the two leptons,

FIG. 35. The scales applied to the transverse momentum in the three removed muon towers in the simulation (solid lines), as functions of  $u_{\parallel}$  (top),  $u_{\perp}$  (middle), and  $\eta$  (bottom). The circles show the scales measured using towers separated in  $\phi$  from the muon in  $W \rightarrow \mu\nu$  data. The scaling functions for removed electron towers have similar shapes.

FIG. 36. The definitions of the  $\eta$  and  $\xi$  axes in  $Z$  boson events. The quark and gluon radiation from the boson production points predominantly in the  $-\eta$  direction.

whose angles are precisely measured. The orthogonal axis is denoted as the “ $\xi$ ” axis.

### 1. Recoil energy scale

We tune the simulation to match the observed detector response to the recoil radiation. The recoil response is defined as  $R \equiv \vec{u}_T^{\text{meas}} \cdot \hat{u}_T^{\text{true}} / u_T^{\text{true}}$ , where  $\vec{u}_T^{\text{true}} = -\vec{p}_T^Z$  is the generated net  $\vec{p}_T$  of the initial-state radiation, and  $\vec{u}_T^{\text{meas}}$  is the reconstructed vector of this transverse momentum.

To simulate the measured recoil, we parametrize the response as

$$R(A, B) = A \ln(u_T^{\text{true}} + B) / \ln(15 + B), \quad (35)$$

where  $u_T^{\text{true}}$  is in units of GeV, and  $A$  and  $B$  are constants determined from the data. Figure 37 shows  $-\vec{u}_T^{\text{meas}} \cdot \hat{p}_T^{\mu\mu} / p_T^{\mu\mu}$ , which approximates  $R$ , for  $Z$  boson decays to muons. The response  $R$  is less than 1 due to calorimeter energy loss from particles curling in the tracker, particles passing through calorimeter cracks, and nonlinearity of the hadronic calorimeter response.

Projecting the lepton momenta and the recoil along the  $\eta$  axis to obtain  $p_{\eta}^l$  and  $u_{\eta}$ , the sum  $p_{\eta}^l + u_{\eta}$  is sensitive to  $R$ . This sum is zero for  $R = 1$ , and positive for  $R < 1$ . We measure  $A = 0.635 \pm 0.007(\text{stat})$  and  $B = 6.68 \pm 1.04(\text{stat})$  by minimizing the combined  $\chi^2$  of the electron and muon ( $p_{\eta}^l + u_{\eta}$ ) distributions as a function of  $p_T^l$  (Fig. 38). We determine  $A$  and  $B$  with the ( $p_{\eta}^l + u_{\eta}$ ) distribution rather than the distribution of Fig. 37 because ( $p_{\eta}^l + u_{\eta}$ ) is well defined as  $p_T^Z \rightarrow 0$  GeV, while  $R$  is not. The parameters  $A$  and  $B$  are statistically uncorrelated by construction. We apply  $R(A, B)$  to the generated recoil  $\vec{u}_T$  in simulated  $W$  and  $Z$  boson events.

FIG. 37. The mean  $-\vec{u}_T^{\text{meas}} \cdot \hat{p}_T^{\mu\mu} / p_T^{\mu\mu}$ , which approximates the recoil response  $R$ , as a function of dimuon  $p_T$  for  $m_{\mu\mu}$  in the  $Z$  boson mass region. The simulation (lines) uses parameters fit from the electron and muon  $p_{\eta}^l + u_{\eta}$  distributions, and models the data (circles) well.

FIG. 38. The simulation (lines) and data (circles) distributions of  $(p_\eta^{ll} + u_\eta)$  for  $Z$  boson decays to muons (top) and electrons (bottom). The combined  $\chi^2$  is minimized in the fit for the recoil detector response parameters.

## 2. Spectator and additional $p\bar{p}$ interactions

The net  $\vec{p}_T$  flow from spectator quarks and additional interactions is negligible due to momentum conservation. However, detector resolution causes its measurement to generally be nonzero. The resolution is predominantly determined by the energy sampling in the calorimeter, and we expect it to increase as the square root of  $\sum p_T$ , the scalar sum of the calorimeter tower  $p_T$ . We plot the width of the  $\vec{p}_T$  distribution, projected along the  $x$  and  $y$  axes, as a function of the  $\sum p_T$  in minimum bias data. We parametrize the dependence as a power law, with the fitted result:

$$\sigma_{x,y} = 0.3842 \left( \sum p_T \right)^{0.5333} \text{ GeV}, \quad (36)$$

where  $\sum p_T$  is defined in units of GeV. The distribution of  $\sum p_T$  from additional interactions, denoted  $P_{\text{MB}}$ , is parametrized as (Fig. 39)

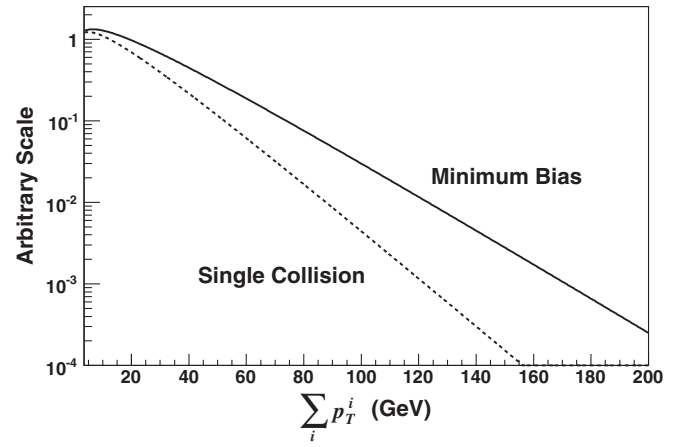

FIG. 39. The  $\sum_i p_T^i$  distribution for minimum bias data (solid line) and a single  $p\bar{p}$  collision (dashed line), as derived from the minimum bias distribution.

$$P_{\text{MB}} \left( \sum p_T \right) \propto \left( \sum p_T \right)^{0.325} e^{-\sum p_T / 19.98}, \quad (37)$$

with constants obtained from a fit to the minimum bias data. In our simulation, we draw a value of  $\sum p_T$  from this distribution, for the fraction of events containing at least one  $p\bar{p}$  collision beyond that producing the  $W$  or  $Z$  boson. This fraction is calculated from the average instantaneous luminosity of  $2.137(2.014) \times 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$  for  $W$  and  $Z$  boson data in the muon (electron) channel, and the assumed instantaneous luminosity per additional collision ( $3.3 \times 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$ ).

The observed  $\sum p_T$  from spectator partons in the  $p\bar{p} \rightarrow W$  or  $Z$  boson interaction is modeled from the minimum bias data, which correspond to one or more  $p\bar{p}$  collisions. We deconvolute the  $\sum p_T$  spectrum of Eq. (37) with the distribution of the number of collisions in minimum bias data to derive the following single-collision  $\sum p_T$  distribution  $P_{1\text{-col}}$  applicable to  $W$  or  $Z$  production (Fig. 39):

$$P_{1\text{-col}} \left( \sum p_T \right) \propto \left( \sum p_T \right)^{0.345} e^{-\sum p_T / 14.27}. \quad (38)$$

The  $\sum p_T$  produced in a single minimum bias collision can be different from that produced by the spectator partons in  $W$  or  $Z$  boson production. In order to allow for a difference, we scale the  $\sum p_T$  drawn from the single-collision spectrum by a parameter  $N_{W,Z}$ , which we tune on the  $Z$  boson data.

With this model, the  $\sum p_T$  in a simulated event is obtained by adding the contributions from the spectator partons and the additional interactions. The corresponding recoil resolution is generated according to Eq. (36), with a single tunable parameter  $N_{W,Z}$ .

FIG. 40. The angle between the measured recoil and the direction opposite  $p_T^l$ , for simulation (histogram) and data (circles) events where the  $Z$  boson decays to muons (top) or electrons (bottom). The  $\chi^2$  from the  $Z \rightarrow \mu\mu$  sample is minimized in the fit to the recoil angular resolution. The corresponding uncertainty on  $m_W$  is negligible.

### 3. Recoil energy resolution

The measurement of the quark and gluon radiation is affected by detector energy resolution, which in turn affects the measured recoil direction. We model the recoil angular resolution as a Gaussian distribution with  $\sigma_\phi = 0.14 \pm 0.01$ (stat), determined from fits to the  $\Delta\phi(\vec{u}_T, -\vec{p}_T^l)$  distribution in  $Z$  boson events (Fig. 40). Since the lepton directions are precisely measured, the width of the peak at  $\Delta\phi = 0$  is dominated by the recoil angular resolution.

The energy resolution of the quark and gluon radiation is predominantly determined by stochastic fluctuations in the hadronic calorimeter, which motivate the functional form  $\sigma_{u_T} \propto \sqrt{u_T^{\text{true}}}$ . We measure the proportionality constant  $s_{\text{hard}}$  using  $Z$  boson data.

To tune  $s_{\text{hard}}$  and  $N_{W,Z}$ , we project the momentum imbalance  $\vec{p}_T^l + \vec{u}_T$  along the  $\eta$  and  $\xi$  axes in  $Z$  boson decays (Fig. 41). The width of these projections as a function of  $p_T^l$

FIG. 41. The simulation (lines) and data (circles)  $p_T^l + u_\eta$  (top) and  $p_T^l + u_\xi$  (bottom) resolutions for  $Z$  boson decays to muons and electrons. The sum of the four  $\chi^2$  values is minimized in the fit for the recoil resolution parameters  $N_{W,Z}$  and  $s_{\text{hard}}$ . Since there are four distributions and two fit parameters, each distribution contributes half a degree of freedom to the fit.

provides information on  $N_{W,Z}$  and  $s_{\text{hard}}$ . At low  $p_T^Z$  the resolution is dominantly affected by  $N_{W,Z}$ , with the  $s_{\text{hard}}$  contribution increasing as the boson  $p_T$  increases. We compare the widths of the data and simulation projections as a function of  $p_T^l$  and compute the  $\chi^2$ . Minimizing this  $\chi^2$ , we obtain  $N_{W,Z} = 1.167 \pm 0.026(\text{stat})$  and  $s_{\text{hard}} = [0.828 \pm 0.028(\text{stat})] \text{ GeV}^{1/2}$ . The tuning is performed such that the statistical uncertainties on these parameters are uncorrelated.

#### D. Recoil model cross-checks

The full recoil model, with parameters tuned from  $Z$  boson events, is applied to the simulated  $W$  boson sample. We compare the data to the predictions of distributions that can affect the final mass measurement: the projections of the recoil along ( $u_{\parallel}$ ) and perpendicular to ( $u_{\perp}$ ) the charged lepton; and the total recoil  $u_T$ .

The  $u_{\parallel}$  distribution is directly affected by the measurements of lepton efficiency as a function of  $u_{\parallel}$  (Figs. 14 and 16) and the modeling of lepton tower removal (Figs. 33 and 34). The  $u_{\parallel}$  is also sensitive to the boson  $p_T$  (Sec. IX B) and decay angular distributions, and to the recoil response and resolutions.

Since  $u_T$  is much less than the charged lepton  $p_T$  for our event selection,  $\not{p}_T \approx |p_T + u_{\parallel}|$ . Thus,  $m_T$  can be written as

$$m_T \approx 2p_T \sqrt{1 + u_{\parallel}/p_T} \approx 2p_T + u_{\parallel}. \quad (39)$$

To a good approximation, any bias in  $u_{\parallel}$  directly enters as a bias in the  $m_T$  fit. We compare the  $u_{\parallel}$  distributions in data and simulation in Fig. 42, and observe no evidence of a bias at the level of the data statistics and simulation systematics derived from the recoil model parameters. All backgrounds

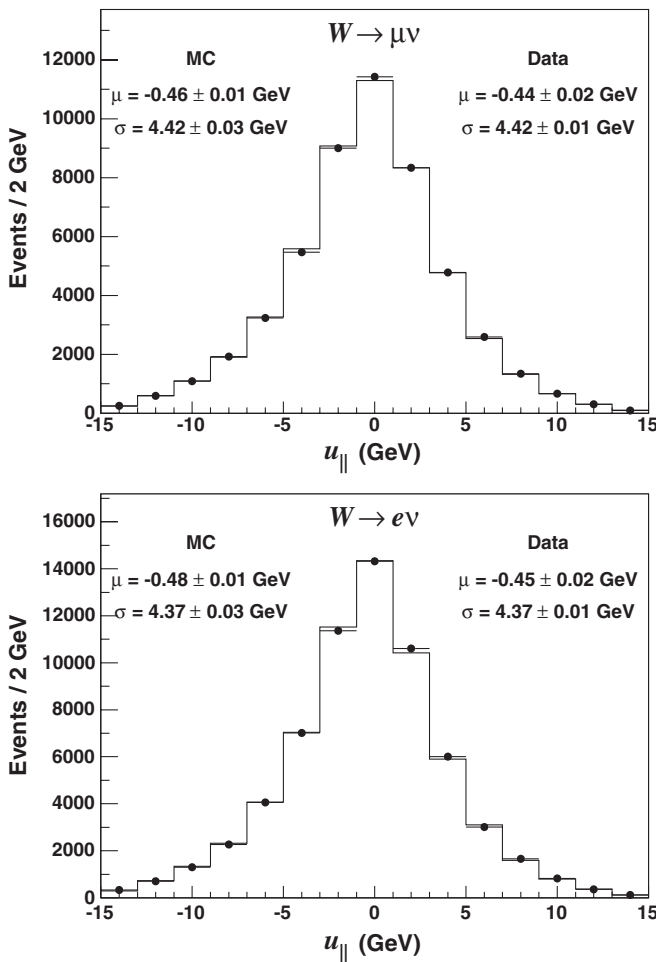

FIG. 42. The simulation (solid line) and data (circles)  $u_{\parallel}$  distributions for  $W$  boson decays to  $\mu\nu$  (top) and  $e\nu$  (bottom). The simulation uses parameters fit from  $Z$  boson data, and the uncertainty on the simulation is due to the statistical uncertainty on these parameters. The data mean ( $\mu$ ) and RMS ( $\sigma$ ) are well modeled by the simulation.

FIG. 43. The simulation (solid line) and data (circles)  $u_{\perp}$  distributions for  $W$  boson decays to  $\mu\nu$  (top) and  $e\nu$  (bottom). The simulation uses parameters fit from  $Z$  boson data, and the uncertainty on the simulation is due to the statistical uncertainty on these parameters. The data mean ( $\mu$ ) and RMS ( $\sigma$ ) are well modeled by the simulation.

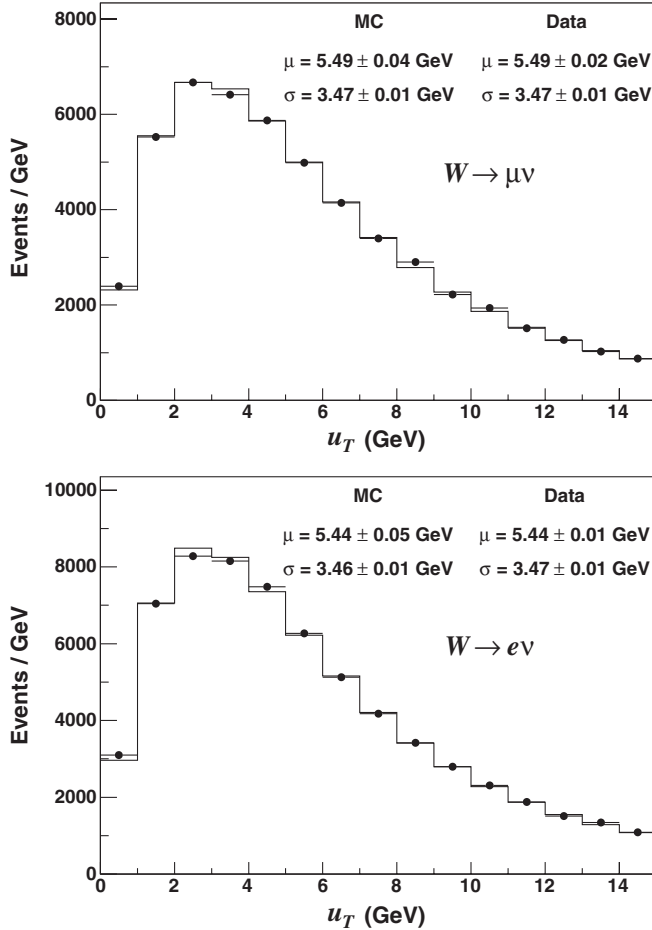

FIG. 44. The simulation (solid line) and data (circles)  $u_T$  distributions for  $W$  boson decays to  $\mu\nu$  (top) and  $e\nu$  (bottom). The simulation uses parameters fit from  $Z$  boson data, and the uncertainty on the simulation is due to the statistical uncertainty on these parameters. The data mean ( $\mu$ ) and RMS ( $\sigma$ ) are well modeled by the simulation.

(Sec. VIII) are included in the comparison, except  $W \rightarrow \tau\nu$ , which has similar distributions to the other  $W$  leptonic decays.

The  $u_{\perp}$  distribution is dominantly affected by the recoil resolution, with a smaller contribution from the recoil response. The simulation models this distribution well for both  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  samples (Fig. 43).

The mean of the  $u_T$  distribution is sensitive to the recoil response and the boson  $p_T$ , and is affected to a lesser extent

TABLE V. Signed shifts in the  $m_W$  fits due to  $1\sigma$  increases in the recoil model parameters.

Input parameter	Shift (MeV)		
	$m_T$	$p_T$	$\cancel{p}_T$
A	-9	-8	2
B	-2	15	15
$N_{W,Z}$	5	0	22
$s_{\text{hard}}$	5	-3	21

by the resolution. The reverse is the case for the RMS of the  $u_T$  distribution. Both are modeled well by the simulation for both  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  samples (Fig. 44).

The uncertainties on the  $m_W$  fits from the recoil parameters (Table V) are determined by varying each parameter by  $\pm 3\sigma$  and assuming linear variation of the fit  $m_W$  with the parameter. Since all uncertainties are uncorrelated, we add them in quadrature to obtain total recoil model uncertainties of 12, 17, and 34 MeV on  $m_W$  from the  $m_T$ ,  $p_T$ , and  $\cancel{p}_T$  fits, respectively. The uncertainties are the same and 100% correlated for the electron and muon channels, since the recoil parameters are obtained from combined fits to  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$  data. The uncertainty on the  $p_T$  fit arises predominantly from the modeling of the  $u_T < 15$  GeV threshold used to select  $W$  boson events (Sec. IV).

## VIII. BACKGROUNDS

The event selection criteria (Sec. IV) result in  $W$  boson samples with high purity. However, the small residual backgrounds affect the distributions used for the  $m_W$  fits. Both the  $W \rightarrow e\nu$  and  $W \rightarrow \mu\nu$  samples receive contributions from  $Z/\gamma^* \rightarrow ll$ , where one lepton is not detected;  $W \rightarrow \tau\nu$ , where the  $\tau$  decay products are reconstructed as a charged lepton; and multijet production, where at least one jet is misreconstructed. The  $W \rightarrow \mu\nu$  sample also contains backgrounds from cosmic rays, where a muon passing through the COT is reconstructed on only one side of the COT, and long-lived hadrons decaying to  $\mu\nu X$ , where the muon momentum is misreconstructed.

### A. $W \rightarrow e\nu$ backgrounds

We model the  $W \rightarrow \tau\nu$  and  $Z/\gamma^* \rightarrow ee$  backgrounds using events generated with PYTHIA [60] and simulated with a full GEANT-based detector simulation [39,40]. The full simulation models global detector inefficiencies and is thus more appropriate for predicting background normalizations than the custom fast simulation. The multijet background is estimated using a data-based approach.

In the standard model the branching ratio for  $W \rightarrow e\nu$  is the same as for  $W \rightarrow \tau\nu$ , neglecting lepton masses. Measurements from LEP [19] test this prediction with a precision of 2.9%, and a slight discrepancy from the standard model is observed with a significance of  $2.6\sigma$ . In estimating the  $W \rightarrow \tau\nu$  background, we assume the standard model prediction and determine the ratio of  $W \rightarrow \tau\nu$  to  $W \rightarrow e\nu$  events from the ratio of acceptances of these two processes, as determined by the full GEANT-based detector simulation. We include an uncertainty of 2.9%, corresponding to the statistical precision of the tests of this assumption. We estimate the  $W \rightarrow \tau\nu$  background to be  $(0.93 \pm 0.03)\%$  of the  $W \rightarrow e\nu$  sample.

The  $Z/\gamma^*$  background is determined from the ratio of  $Z/\gamma^* \rightarrow ee$  to  $W \rightarrow e\nu$  acceptances determined from the GEANT-based detector simulation, multiplied by the corresponding ratio of cross sections times branching ratios. The

ratio  $\sigma \cdot \text{BR}(Z \rightarrow ee)/\sigma \cdot \text{BR}(W \rightarrow e\nu)$  has been calculated in the standard model to be  $10.69 \pm 0.08$  [25,26], and measurements are consistent with this value [26,57,66]. We take an uncertainty of  $\pm 0.43$  on this value from the CDF Run I measurement, and estimate the  $Z/\gamma^* \rightarrow ee$  background in the  $W \rightarrow e\nu$  candidate sample to be  $(0.24 \pm 0.01)\%$ .

Multijet background enters the signal data sample when a hadronic jet is misreconstructed as an electron and a second jet results in large  $\cancel{p}_T$  through energy misreconstruction or the semileptonic decay of a hadron. To estimate this background, we remove the  $\cancel{p}_T$  and  $m_T$  thresholds in our signal event selection to include the background-dominated kinematic region of low  $\cancel{p}_T$ . We then fit the observed  $\cancel{p}_T$  spectrum to the combination of the hadronic jet,  $W \rightarrow e\nu$ ,  $Z/\gamma^* \rightarrow ee$ , and  $W \rightarrow \tau\nu$  components, floating only the hadronic-jet shape normalization (Fig. 45).

In this fit, the  $W \rightarrow e\nu$   $\cancel{p}_T$  distribution is obtained from our fast simulation and normalized to data using the peak region. The shapes and normalizations for the  $Z/\gamma^* \rightarrow ee$  and  $W \rightarrow \tau\nu$  components are determined from the GEANT-based simulation. The shape of the  $\cancel{p}_T$  spectrum of the hadronic-jet background is determined from the single-electron events that pass an antielectron identification requirement based on a neural network discriminant NN. The discriminant is determined by combining the electron quality variables (Sec. IV B) into a neural network [67] trained with single-electron data events, using  $\cancel{p}_T$  to separate signal from background.

Electron candidates in the  $W \rightarrow e\nu$  sample with low NN values have a high probability to be jets misreconstructed

FIG. 45. The  $\cancel{p}_T$  distribution of the  $W \rightarrow e\nu$  candidate sample (triangles) and prediction (solid line), with the  $\cancel{p}_T$  and  $m_T$  selection cuts removed. We fit for the normalization of the hadronic-jet background (dotted line) after fixing the normalization of the  $W \rightarrow e\nu$  distribution (dashed line) in the peak. Not shown are the  $Z/\gamma^* \rightarrow ee$  and  $W \rightarrow \tau\nu$  backgrounds, whose relative normalizations are fixed from the simulation.

as electrons. Events with such candidates provide a  $\cancel{p}_T$  distribution characteristic of hadronic-jet production. We apply a small correction to this distribution to account for the expected contribution from  $W \rightarrow e\nu$  decay electrons with low NN values.

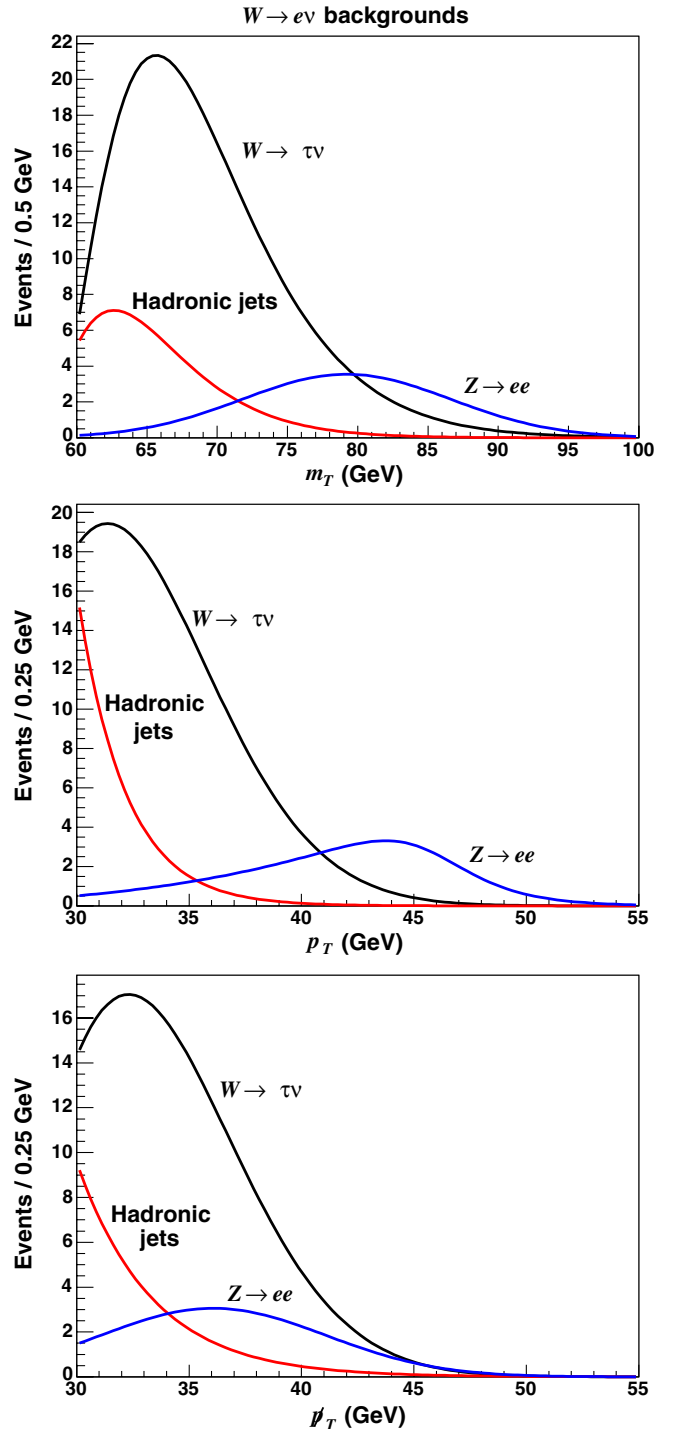

FIG. 46 (color online). The parametrizations of the backgrounds to the  $W \rightarrow e\nu$  data sample. The backgrounds to the  $m_T$  (top),  $p_T$  (middle), and  $\cancel{p}_T$  (bottom) distributions are included in the  $m_W$  fits.

This method relies on the assumption that the hadronic-jet background has a  $\not{p}_T$  distribution that is independent of the electron identification variables. As a test of this assumption, we perform the same fit for the jet background normalization, using only the isolation variable (Sec. IV A) instead of the NN to select a hadronic-jet subsample. We take a weighted average of the two fitted background normalizations, and assign an uncertainty that covers the range of the two results. The resulting background estimate is  $(0.25 \pm 0.15)\%$  of the  $W \rightarrow e\nu$  sample.

The  $m_T$ ,  $p_T$ , and  $\not{p}_T$  distributions are obtained from the GEANT-based simulation for  $W$  and  $Z$  boson backgrounds, and from events in the  $W \rightarrow e\nu$  sample with low-NN electron candidates for the hadronic-jet background. We fit these distributions (Fig. 46) and include their shapes and relative normalizations in the  $m_W$  template fits. The uncertainties on the background estimates result in uncertainties of 8, 9, and 7 MeV on  $m_W$  from the  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits, respectively (Table VI).

### B. $W \rightarrow \mu\nu$ backgrounds

The  $W \rightarrow \tau\nu$  and  $Z/\gamma^* \rightarrow \mu\mu$  backgrounds are modeled using events generated with PYTHIA [60] and simulated with the GEANT [39]-based detector simulation. We use the data to estimate backgrounds from cosmic rays, multijets, and hadrons decaying in flight to  $\mu\nu X$ .

Backgrounds from  $W \rightarrow \tau\nu$  and  $Z/\gamma^* \rightarrow \mu\mu$  to the  $W \rightarrow \mu\nu$  sample are modeled in the same manner as for the  $W \rightarrow e\nu$  sample (Sec. VIII A). We determine the ratio of the acceptance for  $W \rightarrow \tau\nu$  or  $Z/\gamma^* \rightarrow \mu\mu$  events to the acceptance for  $W \rightarrow \mu\nu$  events using the GEANT-based detector simulation. We assume equal branching ratios for the two  $W$  boson decay modes, and use the ratio  $\sigma \cdot \text{BR}(Z \rightarrow \mu\mu)/\sigma \cdot \text{BR}(W \rightarrow \mu\nu) = 10.69 \pm 0.43$  (Sec. VIII A). We estimate the fraction of  $W \rightarrow \tau\nu$  ( $Z/\gamma^* \rightarrow \mu\mu$ ) events in the  $W \rightarrow \mu\nu$  candidate sample to be  $(0.89 \pm 0.02)\%$  [ $(6.6 \pm 0.3)\%$ ]. The  $Z/\gamma^* \rightarrow \mu\mu$  background is large because our event selection does not identify muons with  $|\eta| \geq 1.2$ . The tracker and muon detectors have incomplete or no coverage in the forward rapidity region, and the muons deposit only a few GeV of energy in the calorimeter. Thus, a  $Z/\gamma^* \rightarrow \mu\mu$  event with one central and one forward muon is measured as a single-muon event with large  $\not{p}_T$ .

TABLE VI. The percentages of the various backgrounds in the  $W \rightarrow e\nu$  data set, and the corresponding uncertainties on the  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits for  $m_W$ .

Background	% of $W \rightarrow e\nu$ data	$\delta m_W$ (MeV)		
		$m_T$ fit	$p_T$ fit	$\not{p}_T$ fit
$W \rightarrow \tau\nu$	$0.93 \pm 0.03$	2	2	2
Hadronic jets	$0.25 \pm 0.15$	8	9	7
$Z/\gamma^* \rightarrow ee$	$0.24 \pm 0.01$	1	1	0
Total	$1.42 \pm 0.15$	8	9	7

FIG. 47. The  $t_0$  distributions for  $W \rightarrow \mu\nu$  candidates (solid line),  $Z \rightarrow \mu\mu$  candidates (dashed line), and identified cosmic rays (dotted line). For comparison, the distribution from  $Z$  candidates has been normalized to that of the  $W$  candidates, while the cosmic distribution has been normalized to 0.05% of the  $W$  boson sample.

Cosmic-ray muons passing close to the beam line are a source of background to the  $W \rightarrow \mu\nu$  sample when the muon track is reconstructed on only one side of the COT. The cosmic-ray identification algorithm [58] searches for unreconstructed tracks and removes cosmic rays with high efficiency. The residual cosmic-ray background is estimated using the reconstructed interaction time  $t_0$  and impact parameter  $d_0$  from the COT track fit. Figure 47 compares the  $t_0$  distributions of the  $W \rightarrow \mu\nu$  candidate sample,  $Z/\gamma^* \rightarrow \mu\mu$  candidates, and identified cosmic rays. The cosmic-ray fraction is fit by minimizing the  $\chi^2$  of the sum of the  $Z/\gamma^* \rightarrow \mu\mu$  and cosmic-ray distributions with respect to the  $W \rightarrow \mu\nu$  distribution. We obtain an alternative background estimate by comparing the  $d_0$  distribution of identified cosmic rays to the  $d_0$  distribution of  $W \rightarrow \mu\nu$  candidates with the  $d_0$  selection cut removed. The high impact parameter region of the  $W$  boson sample is enriched with cosmic rays, and is used to estimate the cosmic-ray background within the selection region  $|d_0| < 1$  mm. We take the cosmic-ray background to be  $(0.05 \pm 0.05)\%$ , where the uncertainty covers the range of results from the two estimates.

Decay of a long-lived meson to a muon can result in a reconstructed track with high momentum and large event  $\not{p}_T$ . A low-momentum pion or kaon ( $\lesssim 10$  GeV) that decays in the tracking chamber can be reconstructed as a high-momentum muon if the decay is in an azimuthal direction opposite the meson's curvature (i.e., a kink in the trajectory). Such misreconstruction typically results in a poor COT track  $\chi^2$  and a large impact parameter. For each of these quantities we obtain a prompt muon distribution from  $Z$  boson decays and a meson decay-in-flight distribution from a sample with the  $W$  boson selection requirements, except for a requirement of either high

TABLE VII. The percentages of the various backgrounds in the  $W \rightarrow \mu\nu$  data set, and the corresponding uncertainties on the  $m_T$ ,  $p_T$ , and  $\cancel{p}_T$  fits for  $m_W$ .

Background	% of $W \rightarrow \mu\nu$ data	$\delta m_W$ (MeV)		
		$m_T$ fit	$p_T$ fit	$\cancel{p}_T$ fit
$Z/\gamma^* \rightarrow \mu\mu$	$6.6 \pm 0.3$	6	11	5
$W \rightarrow \tau\nu$	$0.89 \pm 0.02$	1	7	8
Decays in flight	$0.3 \pm 0.2$	5	13	3
Hadronic jets	$0.1 \pm 0.1$	2	3	4
Cosmic rays	$0.05 \pm 0.05$	2	2	1
Total	$7.9 \pm 0.4$	9	19	11

COT track  $\chi^2$  or high impact parameter. We fit for the background fraction by summing the prompt muon distribution with the decay-in-flight distribution, and minimizing the  $\chi^2$  with respect to the muon distribution from the  $W$  boson sample. We obtain a background fraction of  $(0.3 \pm 0.2)\%$ , where the uncertainty covers the range of the estimates obtained using the COT track  $\chi^2$  and impact parameter distributions.

A separate class of hadronic background results from high-momentum muons from short-lived hadronic decays, or energetic hadrons penetrating the calorimeter to the muon detectors. These background muon candidates are typically accompanied by significant hadronic energy due to an associated hadronic jet, and can be separated using a muon isolation variable. Two such variables are determined by using either calorimeter energy or track momenta in an  $\eta - \phi$  cone of size 0.4 surrounding the muon candidate. Using the low  $\cancel{p}_T$  region to select a jet-dominated sample, we fit the track and calorimeter isolation distributions of the  $W$  boson candidate sample to the sum of the expected distributions from  $Z \rightarrow \mu\mu$  events and jet-dominated events. As a third method, we fit the  $\cancel{p}_T$  distribution, using muon candidates with high-isolation values to provide the  $\cancel{p}_T$  distribution of the hadronic-jet background. From the range of results of the three methods, we obtain a jet background estimate of  $(0.1 \pm 0.1)\%$ .

The distributions for the  $m_W$  fit variables (Fig. 48) are obtained from the GEANT-based simulation for  $W$  and  $Z$  boson backgrounds, from identified cosmic-ray events for the cosmic-ray background, from events in the  $W \rightarrow \mu\nu$  sample with high isolation for the hadronic-jet background, and from events with  $W \rightarrow \mu\nu$  selection except for high  $\chi^2$  for the decay-in-flight background. Including uncertainties on the shapes of the distributions, the total uncertainties on the background estimates result in uncertainties of 9, 19, and 11 MeV on  $m_W$  from the  $m_T$ ,  $p_T$ , and  $\cancel{p}_T$  fits, respectively (Table VII).

## IX. PRODUCTION AND DECAY MODELS

The measurement of the  $W$  boson mass relies on a complete model of  $W$  and  $Z$  boson production and decay. The production process is described by perturbative QCD

and a parametrization of nonperturbative QCD effects, with parameters determined from global fits to hadron-hadron and lepton-hadron collision data.  $W$  and  $Z$  boson decays are modeled using a next-to-leading-order electro-weak calculation and include QCD corrections for the lepton angular distributions, as a function of boson  $p_T$ . The most important process in the decay is photon radiation off the final-state charged lepton, which has been calculated at next to leading order [63].

### A. Parton distribution functions

The longitudinal momentum of the produced  $W$  or  $Z$  boson depends on the momenta of the interacting partons. These momenta, generally expressed in terms of the fractions  $x_i$  of the colliding (anti)proton energies, are not known on an event-by-event basis. The  $x_i$  parton distribution functions (PDFs) are however well constrained by hadron-hadron and lepton-hadron collision data. The distributions have been parametrized as simple functional forms for the quarks, antiquarks, and gluons inside a proton. Two independent fits to the global data, performed by the MRST [23] and CTEQ [24] collaborations, constrain the parameters in these PDFs.

We model the quark momentum fractions using the next-to-leading-order CTEQ6M parton distribution functions. The CTEQ parametrization [24] for most of the distribution functions inside the proton is

$$x_p f_a(x_p, Q_0) = A_0 x_p^{A_1} (1 - x_p)^{A_2} e^{A_3 x_p} (1 + A_4 x_p)^{A_5}, \quad (40)$$

where  $f_a$  are the distributions of a particular quark or gluon combination  $a$ ,  $A_i$  are the fit parameters, and  $Q_0$  is the energy scale at which the parameters are defined. The functions at a particular energy scale  $Q$  are determined by a perturbative evolution calculation known as the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi equation [68].

The uncertainty on the  $m_W$  measurement arising from uncertainties on the PDF parameters is determined using a set of 40 PDFs provided by the CTEQ collaboration. The set covers the  $\pm 1.6\sigma$  (90% C.L.) uncertainties [69] for the eigenvectors of the parametrization. The mass shift of a particular  $+1.6\sigma$  PDF, relative to the corresponding  $-1.6\sigma$  PDF, determines the uncertainty due to that eigen-

vector. We calculate the total PDF uncertainty using the quadrature sum of all eigenvector contributions [24]:

$$\delta m_W^{\text{PDF}} = \frac{1}{1.6} \left[ \frac{1}{2} \sqrt{\sum_i (m_W^{i+} - m_W^{i-})^2} \right], \quad (41)$$

where  $m_W^{i\pm}$  represents the mass fits for the  $\pm 1.6\sigma$  shifts in eigenvector  $i$ . These fits are performed using templates and simulated pseudoexperiments, both generated with PYTHIA [60]. The resulting  $\delta m_W^{\text{PDF}}$  are 11, 20, and 13 MeV, for the  $m_T$ ,  $p_T$ , and  $\cancel{p}_T$  fits, respectively. A fit to pseudodata using the MRST PDF set results in  $m_W$  shifts smaller than these uncertainties.

## B. $W$ and $Z$ boson $p_T$

Because mass is a Lorentz invariant, the  $W$  boson transverse mass is only weakly sensitive to the  $W$  boson transverse momentum  $p_T^W$ . However, the decay lepton  $p_T$  spectra are more significantly affected by the  $p_T^W$  distribution.

FIG. 48 (color online). The parametrizations of the backgrounds to the  $W \rightarrow \mu\nu$  data sample. The backgrounds to the  $m_T$  (top),  $p_T$  (middle), and  $\cancel{p}_T$  (bottom) distributions are included in the  $m_W$  fits. Not shown are the small hadronic-jet and cosmic-ray background distributions.

FIG. 49. The simulation (solid line) and data (circles)  $p_T^Z$  distributions for  $Z$  boson decays to  $\mu\mu$  (top) and  $ee$  (bottom). The distributions are used to fit for the nonperturbative parameter  $g_2$ , which determines the most probable value of  $p_T^Z$ . Since there are two distributions for one fit parameter, each distribution contributes half of a degree of freedom. The mean ( $\mu$ ) and RMS ( $\sigma$ ) are consistent between data and simulation.

At the Tevatron, the  $p_T$  spectra of  $W$  and  $Z$  bosons peak at a few GeV (Fig. 49), where the shapes are predominantly determined by nonperturbative QCD interactions. We model the distribution with the RESBOS generator [62], which uses the Collins-Soper-Sterman [70] resummation formalism and a parametrized nonperturbative form factor. In this formalism, the cross section for  $W$  boson production is written as

$$\begin{aligned} \frac{d\sigma(p\bar{p} \rightarrow W + X)}{d\hat{s}d^2\vec{p}_T^W dy} &= \frac{1}{2\pi^2} \delta(\hat{s} - m_W^2) \\ &\times \int d^2b e^{i\vec{p}_T^W \cdot \vec{b}} \tilde{W}_{jk}(\vec{b}, \hat{s}, x_i) \\ &+ Y(p_T^W, \hat{s}, x_i), \end{aligned} \quad (42)$$

where  $x_i$  are the parton energy fractions of the (anti)proton,  $y = 0.5 \ln(x_p/x_{\bar{p}})$  is the boson rapidity,  $\vec{b}$  is the relative impact parameter of the partons in the collision,  $Y$  is a function calculable at fixed order, and  $\tilde{W}$  can be separated into its perturbative and nonperturbative components. We use the Brock-Landry-Nadolsky-Yuan form for the non-perturbative component:

$$\tilde{W}_{jk}^{\text{NP}} = e^{[g_1 - g_2 \ln(Q/2Q_0) - g_1 g_3 \ln(100x_p x_{\bar{p}})]b^2}, \quad (43)$$

where  $Q_0 = 1.6$  GeV and  $g_i$  are parameters suggested by the Collins-Soper-Sterman formalism to be universal to processes with initial-state quarks and colorless objects in the final state [62].

The  $g_2$  parameter affects the position of the most probable  $p_T^W$  and is the most relevant for the  $m_W$  measurement. We use  $g_1 = 0.21$  GeV<sup>2</sup>,  $g_2 = 0.68$  GeV<sup>2</sup>, and  $g_3 = -0.60$ , which are determined from fits to global Drell-Yan data [62]. We verify the applicability of these values to our data by fitting the dilepton  $p_T$  distribution (Fig. 49) for  $g_2$ . We find  $g_2 = [0.685 \pm 0.048(\text{stat})]$  GeV<sup>2</sup>, consistent with the global fits. Systematic uncertainties from lepton resolution and background are negligible.

Varying  $g_2$  by  $\pm 3\sigma$  in pseudoexperiments and taking the fit  $m_W$  to be linearly dependent on  $g_2$ , we find that the uncertainty of  $\delta g_2 = 0.048$  GeV<sup>2</sup> results in uncertainties of 3, 9, and 5 MeV, on  $m_W$  for the  $m_T$ ,  $p_T$ , and  $\hat{p}_T$  fits, respectively. These uncertainties are the same and 100% correlated between the electron and muon channels, since  $g_2$  is fit using  $Z \rightarrow ee$  and  $Z \rightarrow \mu\mu$ . For a given PDF, we find that uncertainties on the other  $g_i$  do not significantly affect the  $m_W$  measurement.

### C. $W$ boson decay

The  $m_W$  measurement is sensitive to the charged lepton decay angle relative to the boson  $p_T$ . The mismodeling of this angle can bias the projection of the recoil along the lepton ( $u_{||}$ ), which in turn affects  $m_W$  measured from the  $m_T$  fit (Sec. VIII D).

The lepton decay angle is predicted by the matrix element calculation in the RESBOS generator, which computes the differential cross section  $\frac{d^4\sigma}{dp_T^W dy_W dQ^2 d\Omega}$ . The angular distributions are defined in the Collins-Soper rest frame of the  $W$  boson [71]. In this frame, the  $z$  axis is defined to bisect the angle between the proton momentum and the opposite of the antiproton momentum.

The angular component of the differential cross section can be written as [72]

$$\begin{aligned} \frac{d\sigma}{d\Omega} &\propto (1 + \cos^2\theta) + \frac{1}{2}A_0(1 - 3\cos^2\theta) + A_1 \sin 2\theta \cos\phi \\ &+ \frac{1}{2}A_2 \sin^2\theta \cos 2\phi + A_3 \sin\theta \cos\phi + A_4 \cos\theta \\ &+ A_5 \sin^2\theta \sin 2\phi + A_6 \sin 2\theta \sin\phi + A_7 \sin\theta \sin\phi, \end{aligned} \quad (44)$$

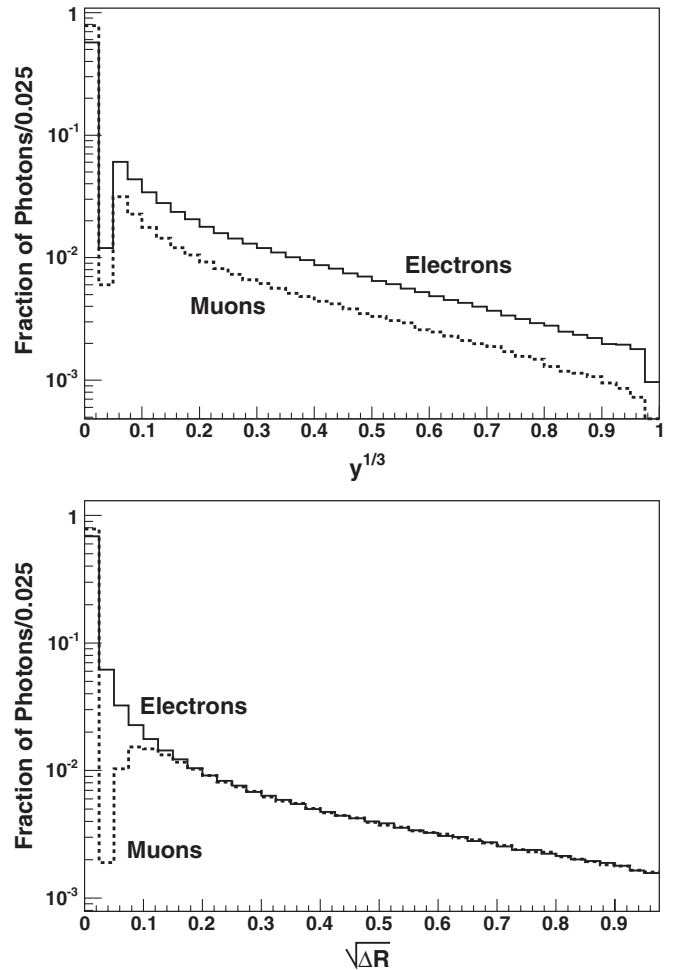

FIG. 50. The cube root of the fraction of electron (solid line) or muon (dashed line) momentum contained in the radiated photon (top), and the square root of the angle  $\Delta R$  (bottom) between the radiated photon and the electron (solid line) or muon (dashed line). The first two bins in the  $y^{1/3}$  distribution correspond to photons of energy  $E_\gamma \leq 5$  MeV for leptons with energy  $E_l = 40$  GeV.

where the  $A_i(p_T^W, y_W)$  have been calculated to next-to-leading order in  $\alpha_s$ . Because of the  $V - A$  structure of the electroweak interaction, for leading-order valence quark interactions all  $A_i$  are zero except  $A_4 = 2$ . The  $A_i$  can be determined experimentally through a moments analysis [73] of the lepton angle in the Collins-Soper frame.

We have performed a moments analysis to extract the  $A_i$  from the RESBOS generator, and compared the results to those obtained [73] from the DYRAD event generator [74], which produces  $W + \text{jet}$  events to order  $\alpha_s^2$ . The two generators give consistent results in the overlapping region  $15 \text{ GeV} < p_T^W < 100 \text{ GeV}$ .

#### D. Photon radiation

The quarks, the  $W$  boson, and the charged lepton have nonzero electromagnetic charge and can radiate photons in the  $W$  boson production process. Radiation off the initial-state quarks and the  $W$  boson propagator have a negligible effect on the invariant mass distribution of the  $W$  boson. Radiation off the final-state charged lepton reduces the measured transverse mass (relative to the  $W$  boson mass) and must be accurately modeled.

We study photon radiation using the WGRAD event generator [63], which models the full next-to-leading-order (NLO) electroweak physics. The generator allows an independent study of photon radiation from the initial-state quarks (ISR), the  $W$  boson propagator, and the final-state charged lepton (FSR). Interference between the contributing diagrams can also be studied independently. We verify that the initial-state, propagator, and interference effects do not affect the measured  $W$  boson mass, within the 5 MeV statistical uncertainty of the simulation.

We simulate final-state photon radiation in our RESBOS-generated  $W$  and  $Z$  boson events by generating a photon for each charged lepton. The energy and angular spectra are taken from the WGRAD generator using the appropriate boson mass. To avoid the infrared divergence that arises when the photon momentum goes to zero, we require  $E_\gamma > \delta_s \sqrt{\hat{s}}/2$ , where  $\delta_s = 10^{-4}$ . We find that increasing  $\delta_s$  to  $10^{-3}$  does not affect the  $m_W$  measurement, at the level of the 5 MeV statistical precision of the tests.

TABLE VIII. The mass shifts obtained by fitting events generated with our simulation of single-photon radiation to templates generated without final-state photon radiation. The shifts are for the  $W$  boson  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits, and for the  $Z$  boson  $m_{ll}$  fit. The shifts have statistical uncertainties of 7 MeV each.

Fit	$\delta m_{W,Z}(\mu)$ (MeV)	$\delta m_{W,Z}(e)$ (MeV)
$m_T$	-158	-138
$p_T$	-206	-186
$\not{p}_T$	-77	-59
$m_{ll}$	-196	-215

The energy of a photon in a given event is calculated from the fraction  $y = E_\gamma/E_l$ . The photon angle  $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$  is taken with respect to the charged lepton. To improve the phase space sampling, we sample from a two-dimensional distribution of the variables  $\sqrt{\Delta R}$  and  $y^{1/3}$  when selecting a photon. The individual distributions of these variables are shown in Fig. 50.

We validate our photon simulation by fitting a sample of events generated with FSR using WGRAD to templates generated with leading-order WGRAD and photons simulated according to our model. We find our FSR model to be consistent with that of WGRAD at the level of the 5 MeV statistical precision of the test. The total effect of including FSR is shown in Table VIII. Since FSR reduces the charged lepton momentum, the shift is largest for the  $p_T$  fit and smallest for the  $\not{p}_T$  fit. The effects are smaller for electrons than for muons because the electron calorimeter energy measurement recovers much of the energy of FSR photons.

We approximate the effect of next-to-next-to-leading-order FSR by increasing the photon's momentum fraction ( $y$ ) by 10%, consistent with the results of a study of higher-order photon radiation [75]. We take half the correction as a systematic uncertainty to account for higher-order QED effects.

The total uncertainty due to photon radiation is the quadrature sum of uncertainties on ISR, interference between ISR and FSR, and radiation off the propagator (5 MeV); uncertainty due to the infrared cutoff of the FSR photon (5 MeV); the FSR model (5 MeV); and uncertainties on higher-order FSR corrections (7 MeV for the electron and 8 MeV for the muon  $m_T$  fits). The total uncertainties are 12 (11), 13 (13), and 10 (9) MeV, for the muon (electron)  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits, respectively.

#### X. W BOSON MASS FITS

We fit the  $W$  boson data distributions to a sum of background and simulated signal templates of the  $m_T$ ,  $p_T$ , and  $\not{p}_T$  distributions, fixing the normalization of the sum to the number of data events. The fit minimizes the negative log likelihood (Sec. IID) as a function of the template parameter  $m_W$ , which is defined by the relativistic Breit-Wigner mass distribution [42]:

$$\frac{d\sigma}{dm} \propto \frac{m^2}{(m^2 - m_W^2)^2 + m^4 \Gamma_W^2 / m_W^2}, \quad (45)$$

where  $m$  is the invariant mass of the propagator. The likelihood is calculated in  $m_W$  steps of 1 MeV. We use the standard model  $W$  boson width  $\Gamma_W = 2.094 \text{ GeV}$ , which has an accuracy of 2 MeV and is calculated for  $m_W = 80.393 \text{ GeV}$ . Using pseudoexperiments, we find the input  $\Gamma_W$  affects the fit  $m_W$  according to the relation  $dm_W/d\Gamma_W = 0.14 \pm 0.04$ .

FIG. 51. The simulation (solid line) and data (points)  $m_T$  distributions for  $W$  boson decays to  $\mu\nu$  (top) and  $e\nu$  (bottom). The simulation corresponds to the best-fit  $m_W$ , determined using events between the two arrows. The uncertainty is statistical only. The large  $\chi^2$  for the electron fit is due to individual bin fluctuations (Fig. 55) and does not bias the fit result, as evidenced by the small change in the fit  $m_W$  when the fit window is varied (Fig. 58).

### A. Fit results

The results of the  $m_T$  fits are shown in Fig. 51, and Table IX gives a summary of the 68% confidence level uncertainties associated with the fits. We fit for  $m_W$  in the range  $65 \text{ GeV} < m_T < 90 \text{ GeV}$ , where the fit range has been chosen to minimize the total uncertainty on  $m_W$ . The  $p_T$  and  $\cancel{p}_T$  distributions are fit in the range  $32 \text{ GeV} < p_T < 48 \text{ GeV}$  (Figs. 52 and 53, respectively) and have uncertainties shown in Tables X and XI, respectively. We show the individual fit results in Table XII, and the negative log-likelihoods of all fits in Fig. 54.

We combine results from the  $W \rightarrow \mu\nu$  and  $W \rightarrow e\nu$  fits using the best linear unbiased estimator (BLUE) [76]. The BLUE algorithm defines a procedure for constructing a complete covariance matrix using the derivative of  $m_W$  with respect to each model parameter [18]. We construct this matrix assuming each source of systematic uncertainty is independent of any other source of uncertainty. The resulting covariance matrix (Table XIII) is then used to combine all six  $m_W$  fits. When combining any subset of fits, the appropriate smaller covariance matrix is used.

FIG. 53. The simulation (solid line) and data (points)  $p_T$  distributions for  $W$  boson decays to  $\mu\nu$  (top) and  $e\nu$  (bottom). The simulation corresponds to the best-fit  $m_W$ , determined using events between the two arrows. The uncertainty is statistical only.

TABLE XIV. The statistical correlations between the  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits in the electron and muon decay channels.

Correlation	$W \rightarrow \mu\nu$	$W \rightarrow e\nu$
$m_T - p_T$	70%	68%
$m_T - \not{p}_T$	72%	63%
$p_T - \not{p}_T$	38%	17%

The result of combining the  $m_W$  fits to the  $m_T$  distribution in the  $W \rightarrow \mu\nu$  and  $W \rightarrow e\nu$  channels is

$$m_W = 80.417 \pm 0.048 \text{ GeV.} \quad (46)$$

The  $\chi^2/\text{dof}$  of the combination is 3.2/1 and the probability that two measurements of the same quantity would have a  $\chi^2/\text{dof}$  at least as large as this is 7%.

The combination of the fits to the  $p_T$  distribution yields

$$m_W = 80.388 \pm 0.059 \text{ GeV,} \quad (47)$$

with a  $\chi^2/\text{dof}$  of 1.8/1 and an 18% probability for the two measurements to obtain a  $\chi^2/\text{dof} \geq 1.8$ .

The results of the fits to the  $\not{p}_T$  distribution give

$$m_W = 80.434 \pm 0.065 \text{ GeV,} \quad (48)$$

with a 43% probability of obtaining a  $\chi^2/\text{dof}$  at least as large as observed (0.6/1).

Combining the  $m_T$ ,  $p_T$ , and  $\not{p}_T$  fits within the individual decay channels gives  $m_W = (80.352 \pm 0.060) \text{ GeV}$  with a

FIG. 55. The difference between the data and simulation, divided by the statistical uncertainty on the prediction, for the  $m_T$  distributions in the muon (top) and electron (bottom) channels. The arrows indicate the fit region.

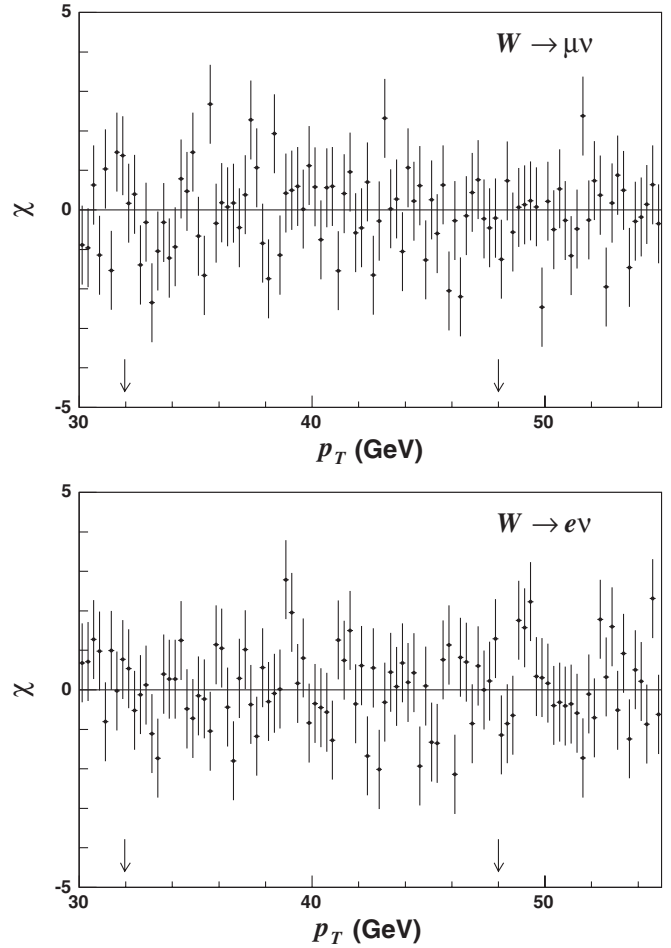

FIG. 56. The difference between the data and simulation, divided by the statistical uncertainty on the prediction, for the  $p_T$  distributions in the muon (top) and electron (bottom) channels. The arrows indicate the fit region.

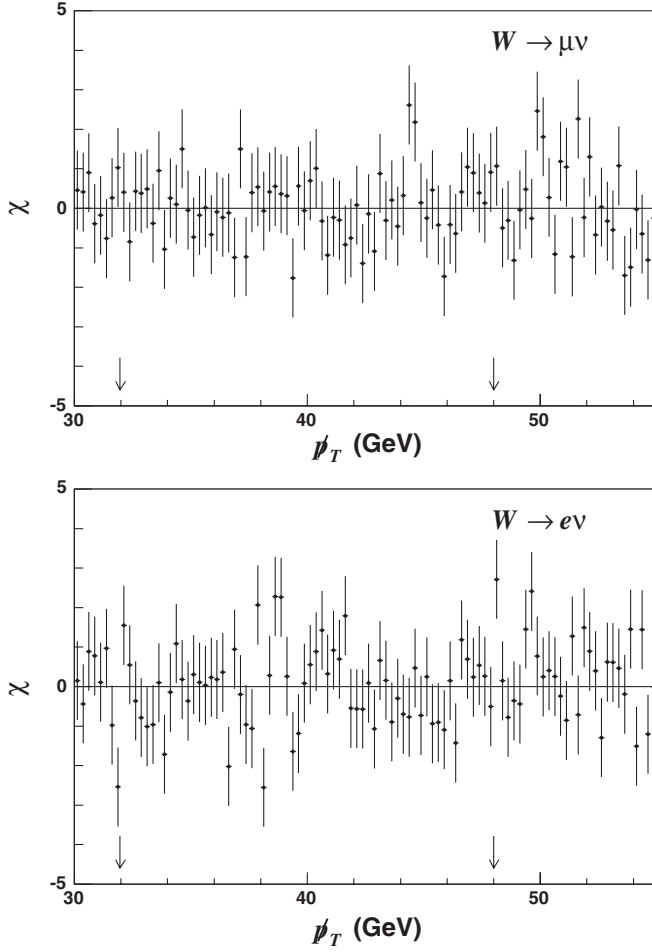

FIG. 57. The difference between the data and simulation, divided by the statistical uncertainty on the data points, for the  $p_T$  distributions in the muon (top) and electron (bottom) channels. The arrows indicate the fit region.

$\chi^2/\text{dof}$  of 1.4/2 for the  $W \rightarrow \mu\nu$  channel and  $m_W = (80.477 \pm 0.062)$  GeV with a  $\chi^2/\text{dof}$  of 0.8/2 for the  $W \rightarrow e\nu$  channel.

We combine the six fits with the BLUE procedure to obtain our final result of

$$m_W = 80.413 \pm 0.048 \text{ GeV}, \quad (49)$$

which has statistical and systematic uncertainties of 34 MeV each. The statistical correlations between the fits, determined from simulation pseudoexperiments, are shown in Table XIV. The relative weights of the fits are 47.7% (32.3%), 3.4% (8.9%), and 0.9% (6.8%) for the  $m_T$ ,  $p_T$ , and  $p_T$  fit distributions, respectively, in the muon (electron) channel. The combination establishes an *a priori* procedure to incorporate all the information from individual fits, and yields a  $\chi^2/\text{dof}$  of 4.8/5. The probability to obtain a  $\chi^2$  at least as large as this is 44%.

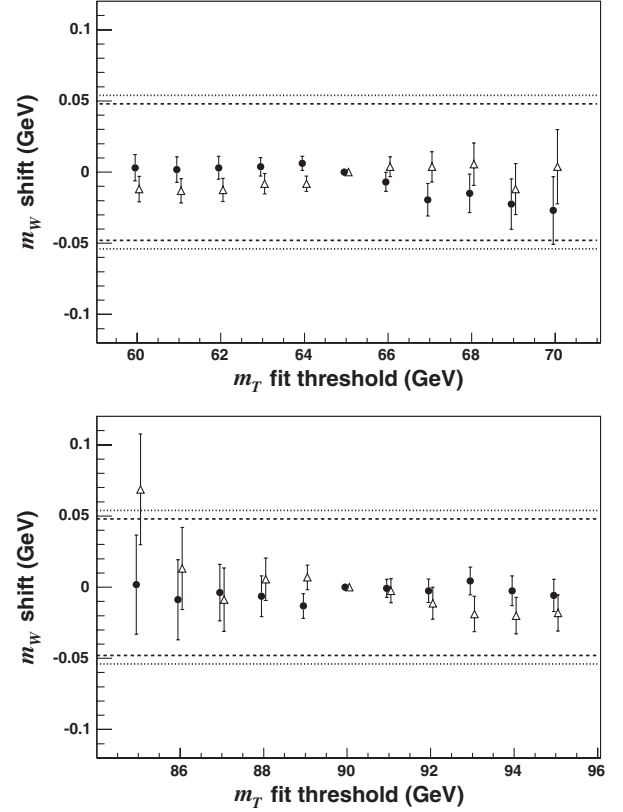

FIG. 58. The shifts in measured  $m_W$  for variations in the lower (top) and upper (bottom) edges of the  $m_T$  fit range. The electron channel is denoted by open triangles and the muon channel by solid circles. The error bars indicate the expected statistical variations from simulation pseudoexperiments. The dashed (dotted) lines indicate the statistical uncertainty on the  $m_W$  fit using the default fit range in the electron (muon) channel.

## B. Cross-checks

Figures 55–57 show the differences between data and simulation, divided by the statistical uncertainties on the predictions, for the  $m_T$ ,  $p_T$ , and  $p_T$  distributions. Figures 58–60 show the variations of the fitted mass values, relative to the nominal results, as the fit regions are varied. These plots show variations consistent with statistical fluctuations.

The variation of the  $p_T$  fits with time, detector region, and lepton charge (Table XV) shows no evidence of dependence on time or detector region. There is a difference between positive and negative lepton mass fits at the level of  $\approx 2\sigma$  in each decay channel. The largest systematic uncertainty in this difference arises in the muon channel from the uncertainty on the alignment parameters  $a_0$  and  $a_2$  (Table III). The uncertainties on the mass difference due to these parameters are 49 MeV and 56 MeV, respectively, for a total uncertainty of 75 MeV. Any bias in these parameters affects the positive and negative lepton fits in opposite directions, and thus has a negligible net effect when the two are combined.

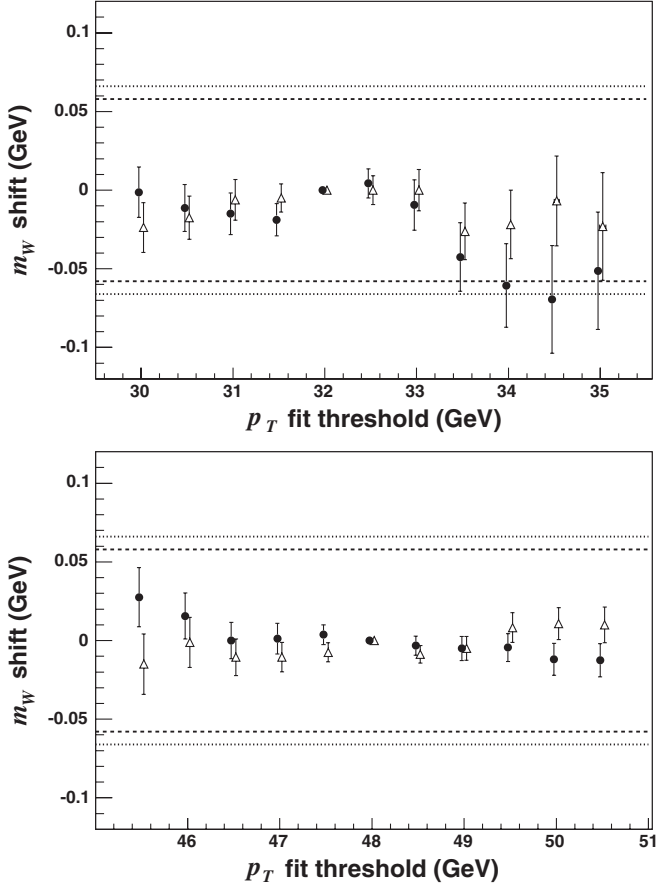

FIG. 59. The shifts in measured  $m_W$  for variations in the lower (top) and upper (bottom) edges of the  $p_T$  fit range. The electron channel is denoted by open triangles and the muon channel by solid circles. The error bars indicate the expected statistical variations from simulation pseudoexperiments. The dashed (dotted) lines indicate the statistical uncertainty on the  $m_W$  fit using the default fit range in the electron (muon) channel.

## XI. SUMMARY

We have performed a measurement of the  $W$  boson mass using  $200 \text{ pb}^{-1}$  of data collected by the CDF II detector at  $\sqrt{s} = 1.96 \text{ TeV}$ . From fits to  $m_T$ ,  $p_T$ , and  $\cancel{p}_T$  distributions of the  $W \rightarrow \mu\nu$  and  $W \rightarrow e\nu$  data samples, we obtain

$$m_W = 80.413 \pm 0.048 \text{ GeV}, \quad (50)$$

which is the single most precise determination of  $m_W$  to date. The uncertainty includes statistical and systematic contributions of 34 MeV each.

Combining this result with the Run I Tevatron measurements using the method in [77], we obtain a CDF Run I/II combined result of

$$m_W = 80.418 \pm 0.042 \text{ GeV}, \quad (51)$$

and a combined Tevatron result of

$$m_W = 80.429 \pm 0.039 \text{ GeV}. \quad (52)$$

FIG. 60. The shifts in measured  $m_W$  for variations in the lower (top) and upper (bottom) edges of the  $\cancel{p}_T$  fit range. The electron channel is denoted by open triangles and the muon channel by solid circles. The error bars indicate the expected statistical variations from simulation pseudoexperiments. The dashed (dotted) lines indicate the statistical uncertainty on the  $m_W$  fit using the default fit range in the electron (muon) channel.

In these combinations, we take the uncertainties due to PDFs and photon radiation to be fully correlated between our measurement and the previous Tevatron measurements. In the BLUE combination method [76], each uncertainty source contributes its covariance matrix, and all covariance matrices are summed to obtain the total covariance matrix. We evaluate an individual contribution to the uncertainty on our result by ignoring its respective covariance matrix and repeating the sixfold combination of our individual electron and muon channel  $m_T$ ,  $p_T$ , and  $\cancel{p}_T$  fits. The difference in quadrature between the total uncertainty, including and excluding a given covariance matrix contribution, is taken to be the uncertainty due to that source. Following this procedure, we obtain the systematic uncertainty contributions due to PDFs and QED radiative corrections to be 12.6 MeV and 11.6 MeV, respectively (Table XVI), for a combined uncertainty of 17.2 MeV.

Assuming no correlation between the Tevatron and LEP measurements, we obtain a new world average of

TABLE XV. Differences of  $m_W$  in the  $p_T$  fits between positively and negatively charged leptons, leptons in the upper and lower halves of the detector, and early and late data. The units are MeV.

Fit difference	$W \rightarrow \mu\nu$	$W \rightarrow e\nu$

$m_W(\phi_l > 0) - m_W(\phi_l < 0)$	$0 \pm 133$	$116 \pm 117$
$m_W$ (Mar. 2002–Apr. 2003)–	$75 \pm 135$	$-107 \pm 117$
$m_W$ (Apr. 2003–Sept. 2003)		

TABLE XVI. Systematic uncertainties in units of MeV on the combination of the six fits in the electron and muon channels. Each uncertainty has been estimated by removing its covariance and repeating the sixfold combination.

Source	Uncertainty (MeV)
Lepton scale	23.1
Lepton resolution	4.4
Lepton efficiency	1.7
Lepton tower removal	6.3
Recoil energy scale	8.3
Recoil energy resolution	9.6
Backgrounds	6.4
PDFs	12.6
$W$ boson $p_T$	3.9
Photon radiation	11.6

$$m_W = 80.398 \pm 0.025 \text{ GeV.} \quad (53)$$

Our measurement reduces the world uncertainty to 31 parts in  $10^5$ , and further constrains the properties of the Higgs boson and other new particles coupling to the  $W$  and  $Z$  bosons. Within the context of the standard model, fits made to high-energy precision electroweak data in 2006 gave  $m_H = 85_{-28}^{+39}$  GeV, with  $m_H < 166$  GeV at the 95% confidence level [19]. The values used for the top quark and  $W$  boson masses in these fits were  $m_t = (171.4 \pm 2.1)$  GeV and  $m_W = (80.392 \pm 0.029)$  GeV, respectively. Updating these fits with the most recent world-average values of  $m_t = (170.9 \pm 1.8)$  GeV and  $m_W = (80.398 \pm 0.025)$  GeV [Eq. (53)], and using the methods and data described in [19,78], gives  $m_H = 76_{-24}^{+33}$  GeV, with  $m_H < 144$  GeV at the 95% confidence level. The effect of the new  $m_W$  value alone is to reduce the predicted value of the standard model Higgs boson mass by 6 GeV.

We anticipate a significant reduction in the uncertainty of future CDF  $m_W$  measurements using larger available data sets. The dominant uncertainties on this measurement are due to  $W$  boson statistics and to the lepton energy scale calibration (Table XVI), and will be reduced with increased statistics in the  $W$  boson and calibration data samples.

## APPENDIX: ELECTRON AND PHOTON INTERACTIONS

The simulation of electrons and photons (Sec. III B 2) uses the Bethe-Heitler differential cross sections for electron bremsstrahlung and photon conversion [49]. Defining  $y$  as the final-state photon energy divided by the initial-state electron energy, the bremsstrahlung cross section is

$$\frac{d\sigma}{dy} = 4\alpha_{\text{EM}}r_e^2 \left[ \left( \frac{4}{3y} - \frac{4}{3} + y \right) \psi_1(Z) + \left( \frac{1}{y} - 1 \right) \frac{\psi_2(Z)}{9} \right], \quad (A1)$$

where

$$\begin{aligned} \psi_1(Z) &= Z^2 [\ln(184.15Z^{-1/3}) - f] + Z \ln(1194Z^{-2/3}), \\ \psi_2(Z) &= Z^2 + Z, \\ f &= a^2 [(1 + a^2)^{-1} + 0.20206 - 0.0369a^2 \\ &\quad + 0.0083a^4 - 0.002a^6], \end{aligned} \quad (A2)$$

and  $a = \alpha_{\text{EM}}Z$ . We define a material's radiation length  $X_0$  according to [49]

$$X_0^{-1} \equiv 4\alpha_{\text{EM}}r_e^2 N_A \rho \psi_1(Z) / A, \quad (A3)$$

where  $\rho$  is the density of the material. In terms of the radiation length, the cross section is

$$\frac{d\sigma}{dy} = \frac{A}{N_A X_0 \rho} \left[ \left( \frac{4}{3} + C \right) \left( \frac{1}{y} - 1 \right) + y \right], \quad (A4)$$

where

$$C \equiv \frac{\psi_2(Z)/9}{\psi_1(Z)}. \quad (\text{A5})$$

The conversion cross section takes a similar form, since the relevant Feynman diagram is a rotation of the bremsstrahlung process [49]:

$$\frac{d\sigma}{dy} = \frac{A}{N_A X_0 \rho} [1 - (4/3 + C)y(1 - y)]. \quad (\text{A6})$$

The Compton scattering cross section as a function of scattering angle is given by the Klein-Nishina formula [55]:

$$\frac{d\sigma}{d\Omega} = \frac{r_e^2}{2} \left[ \frac{1 + \cos^2\theta}{[1 + k(1 - \cos\theta)]^2} + \frac{k^2(1 - \cos\theta)^2}{[1 + k(1 - \cos\theta)]^3} \right], \quad (\text{A7})$$

where  $k \equiv E_\gamma/m_e$ . The scattering angle is kinematically related to the energy loss by [55]

$$y = k'/k = [1 + k(1 - \cos\theta)]^{-1}, \quad (\text{A8})$$

where  $k'$  is the energy of the photon after scattering, in units of  $m_e$ . Using this equation, the differential cross section with respect to  $y$  can be written as [39]

$$\frac{d\sigma}{dy} \propto 1/y + y, \quad (\text{A9})$$

ignoring terms containing  $1/k$ .

- [64] We do not require the correction factor for the number of radiation lengths ( $0.4 \pm 0.9\%$ ) to be the same as that for the ionization energy loss ( $-6 \pm 2\%$ ) because of our assumption that copper cable needs to be added to the GEANT simulation to model the radial distribution of photon conversions. Since the bremsstrahlung and conversion cross sections scale as  $X_0^{-1} \propto Z^2$  (Appendix) and the ionization energy loss scales as  $Z$  (Sec. III B 1), the correction factors can be different if the type of material is incompletely known.
- [65] The statistical significance of the slope in the  $Z$  boson sample is  $0.5\sigma$ . Averaging with the  $W$  boson sample results in zero slope.
