The centisome 63 type III secretion system (T3SS-1) encoded by *Salmonella* pathogenicity island 1 (SPI1) mediates invasion of epithelial cells by *Salmonella enterica* serotype Typhimurium. Characterization of mutants lacking individual genes has revealed that T3SS-1 secreted proteins (effectors) SopE2 and SopB are required for invasion while the SipA protein accelerates entry into cells. Here we have revisited the question of which T3SS-1 effectors contribute to the invasion of epithelial cells by complementing a strain lacking all of the effector genes that are required to cause diarrhea in a calf (a *sipA sopABDE2* mutant). Introduction of either the cloned *sipA*, the cloned *sopB*, or the cloned *sopE2* gene increased the invasiveness of the *sipA sopABDE2* mutant for nonpolarized HT-29 cells. However, a contribution of *sopA* or *sopD* to invasion was not apparent when invasion assays were performed with the nonpolarized colon carcinoma cell lines T84 and HT-29. In contrast, introduction of either the *sopA*, the *sopB*, the *sopD*, or the *sopE2* gene increased the invasiveness of the *sipA sopABDE2* mutant for polarized T84 cells. Furthermore, introduction of a plasmid carrying *sipA* and *sopB* increased the invasiveness of the *sipA sopABDE2* mutant for polarized T84 cells significantly compared to the introduction of plasmids carrying only *sipA* or *sopB*. We conclude that SipA, SopA, SopB, SopD, and SopE2 contribute to *S. enterica* serotype Typhimurium invasion of epithelial cells in vitro.

Invasion of epithelial cells (11) and induction of diarrhea in calves (30, 35) are governed by the centisome 63 type III secretion system (T3SS-1) of *Salmonella enterica* serotype Typhimurium. T3SS-1 secretes proteins, termed effectors, across the inner and outer membranes of the bacterial cell. Some of the secreted effectors, including SipA (SspA), SipB (SspB), SipC (SspC), SptP, and AvrA, are encoded by genes located on SPI1 at centisome 63 of the bacterial chromosome (17, 20, 22–24). The remaining effectors, including SopA, SopB (SigD), SopD, SopE, SopE2, SlrP, and SspH1, are encoded by genes that are scattered around the *S. enterica* serotype Typhimurium chromosome (1, 16, 19, 25, 28, 33, 36). Upon secretion from the bacterial cell, the SipB, SipC, and SipD proteins are thought to form a complex in the eukaryotic membrane that is required for translocation of the remaining effectors into the host cell cytoplasm (3, 10, 12, 17, 37). The T3SS-1-mediated secretion and translocation of effectors trigger the formation of ruffles in the host cell membrane that results in bacterial internalization (9, 13). Characterization of strains carrying mutations in T3SS-1 effector genes suggests that in most *S. enterica* serotype Typhimurium isolates invasion of epithelial cell lines is mediated by translocation of SopB and SopE2 into host cells (26, 43). A small fraction of *S. enterica* serotype Typhimurium isolates carry in addition a bacteriophage (SopEΦ)

encoding the effector SopE, which also contributes to bacterial internalization (16, 18, 26). Strains carrying mutations in both *sopB* and *sopE2* (and isolates carrying SopEΦ in addition to a mutation in *sopE*) are not able to invade nonpolarized epithelial cell lines (26, 43). Inactivation of *sipA* causes a short (5-min) delay during invasion of *S. enterica* serotype Typhimurium into epithelial cell lines, but equal numbers of the wild type and the *sipA* mutant are recovered at later times from gentamicin protection assays (21, 44). T3SS-1 effectors other than SipA, SopB, SopE, and SopE2 have not been implicated in the mediation of bacterial invasion.

Bacterial strains with mutations in individual effector genes have also been used to determine which T3SS-1 effectors contribute to the ability of *S. enterica* serotype Typhimurium to cause diarrhea in calves. Strains carrying mutations in *slrP*, *sptP*, *avrA*, or *sspH1* cause fluid accumulation and neutrophil infiltration in bovine ligated ileal loops at levels similar to those of wild-type *S. enterica* serotype Typhimurium (41). In contrast, mutations in either *sipA*, *sopA*, *sopB*, *sopD*, *sopE2*, or *sopE* (in isolates carrying SopEΦ) cause a significant reduction in fluid accumulation and neutrophil influx (40, 41). However, the molecular mechanisms by which SipA, SopA, SopB, SopD, SopE2, and SopE contribute to inflammation are unknown.

S. enterica serotype Typhimurium causes a neutrophil influx in the bovine intestinal mucosa by inducing the expression of neutrophil chemoattractants (i.e., interleukin-8 and GROα) in epithelial cells in a T3SS-1-dependent manner (39). Studies with colon carcinoma cell lines show that the release of chemoattractants from epithelial cells is triggered through recognition of bacterial molecular patterns (i.e., flagella) by Toll-like

receptors located on their basolateral membrane (i.e., TLR5) (14, 38). One hypothesis is that T3SS-1-mediated invasion of epithelial cells in the bovine mucosa is required for subsequent recognition of bacterial molecular patterns by Toll-like receptors that are located in cellular compartments not accessible from the intestinal lumen. A correlate of this hypothesis is that all of the effectors previously implicated in eliciting inflammation in vivo (41) should also contribute to the invasion of epithelial cells in vitro. The goal of this study was to test this correlate.

Analysis of effectors is complicated by their partial functional redundancy, which may mask the role of an effector in epithelial invasion when the respective mutant is analyzed (26, 43). Previous studies on the role of effectors in epithelial invasion relied on an the analysis of mutants that were still expressing several of the effectors required for fluid accumulation and inflammation in the calf model. In this study, we have taken an alternate approach by using a strain background lacking the expression of all of the effectors required for fluid accumulation and inflammation in the calf model. This approach allowed us to test the contribution of individual effectors in the absence of proteins with functional redundancy. Furthermore, we compared the invasiveness in nonpolarized and polarized colon carcinoma cell lines to ensure that we would be able to identify those effectors that may only be required for invasion of cells containing an apical membrane brush border.

MATERIALS AND METHODS

Bacterial strains, tissue culture cells, and culture conditions. Cloning of T3SS-1 effector genes was performed with *Escherichia coli* strain DH5 α , which has been described previously (15). The *S. enterica* serotype Typhimurium strains used in this study are listed in Table 1. Strains were cultured aerobically at 37°C in Luria-Bertani (LB) broth supplemented with antibiotics as appropriate at the following concentrations: carbenicillin at 100 mg/liter, chloramphenicol at 30 mg/liter, tetracycline at 20 mg/liter, kanamycin at 60 mg/liter, and nalidixic acid

at 50 mg/liter. For invasion assays with tissue explants, tissue culture cells, or bovine ligated ileal loops, each strain was grown overnight at 37°C in 4 ml of LB broth in a roller. A volume of 0.04 ml of this overnight culture was used for inoculation of 4 ml of LB broth, and bacteria were grown at 37°C for 3 h in a roller. Subsequently, this culture was used as the inoculum and numbers of CFU were determined by plating serial 10-fold dilutions on LB plates.

The human colon carcinoma cell line HT-29 has been described previously (8) and was obtained from the American Type Culture Collection (ATCC). HT-29 cells were grown in McCoy's 5a medium with 1.5 mM L-glutamine (Gibco) supplemented with 10% fetal calf serum. For invasion assays, cells were seeded at 2.5×10^5 cells/well in 24-well plates and the invasion assay was performed on the following day. The human colon carcinoma cell line T84 has been described previously (6) and was obtained from ATCC. T84 cells were grown in DMEM/F12 medium (Gibco) containing 1.2 g of sodium bicarbonate per liter, 2.5 mM L-glutamine, 15 mM HEPES, and 0.5 mM sodium pyruvate (Gibco) supplemented with 10% fetal calf serum. For nonpolarized T84 invasion assays, cells were seeded as described above for HT-29 cells. To polarize T84 cells, 0.5 ml of medium containing 4×10^5 cells/well was seeded on the apical compartment in 12-mm-diameter Transwell plates (polycarbonate membrane with a pore size of 0.4 μ m; Corning Costar) and 1.5 ml of medium was added to the basolateral compartment. The medium was changed every other day, and the transepithelial electrical resistance (TER) was measured after a week. When the cells reached a TER of at least 1,500 Ω /cm², they were incubated overnight in fresh medium and the invasion assay was performed on the following day.

Construction of plasmids. The primers used for amplification of the *sipA*, *sopA*, *sopB*, *sopD*, and *sopE2* genes from *S. enterica* serotype Typhimurium strain IR715 by PCR are listed in Table 2. All PCR products were initially cloned into pCR2.1, and amplification of the correct genes was confirmed by sequence analysis. A DNA fragment containing the *sopA* gene and its promoter region was cloned into the ClaI site of the low-copy-number vector pWSK29 to give rise to plasmid pMR28 (Table 1). A DNA fragment containing the *sopE2* gene and its promoter region was cloned into the EcoRI site of pWSK29 to give rise to plasmid pMR17. The *sopA* gene was cloned into the ClaI site of plasmid pMR17 to give rise to plasmid pMR18. A DNA fragment containing the *sopD* gene and its promoter region was cloned into the SacI site of pWSK29 to give rise to plasmid pMR15. The *sipA* gene is located in the *sipBCDA* operon and was amplified without its promoter and cloned directionally behind the *lac* promoter of pWSK29 with BamHI and XbaI to give rise to plasmid pMR29. The *sopB* gene was amplified with its promoter but without a termination loop and cloned into pWSK29 with NotI and XbaI to give rise to plasmid pMR26. The *sipA* gene was introduced in the same orientation and downstream of the *sopB* stop codon into plasmid pMR26 to give rise to plasmid pPW1. The *sopB* and *sipA* genes were

excised from pPW1 with NotI BamHI and cloned into pMR15 to give rise to plasmid pMR24. The *sopA* and *sopE2* genes were excised from pMR18 and cloned into XhoI-BamHI-digested pMR24 to give rise to plasmid pMR31.

Tissue culture invasion assays. Invasion assays were performed by using protocols for gentamicin protection assays described previously (32). In brief, colon carcinoma cells were seeded as described above and infected with *S. enterica* serotype Typhimurium strains at approximately 10⁷ CFU/well. The bacteria were incubated for 1 h at 37°C in 5% CO₂ to allow invasion. Each well was washed five times with sterile phosphate-buffered saline (PBS) (KCl at 2.7 mM, KH₂PO₄ at 1.8 mM, NaCl at 140 mM, Na₂HPO₄ at 10 mM, pH 7.4) to remove extracellular bacteria, and medium containing gentamicin at a concentration of 0.1 mg/ml was added for a 90-min incubation at 37°C in 5% CO₂. After three washes with PBS, the cells were lysed with 0.5 ml of 1% Triton X-100, the lysates were transferred to sterile tubes, and each well was rinsed with 0.5 ml of PBS. Tenfold serial dilutions were plated to count the intracellular bacteria. During assays with polarized T84 cells, cells were washed with Dulbecco's PBS 14040 (CaCl₂ at 100 mg/liter, KCl at 200 mg/liter, KH₂PO₄ at 200 mg/liter, MgCl₂ · 6H₂O at 100 mg/liter, NaCl at 8 g/liter, Na₂HPO₄ · 7H₂O at 2.16 g/liter) (Gibco) instead of PBS and TER was measured before infection and 1 and 2.5 h after infection with a voltmeter (Millipore-ERS resistance meter; Millipore, Bedford, Mass.).

Fluorescence microscopy assay. HT-29 cells were seeded onto coverslips in a 24-well plate. An invasion assay was performed as described above. After treatment with gentamicin, the monolayers were washed three times with PBS and incubated with 3% formaldehyde for 20 min. After three washes with PBS, the coverslips were incubated with 1% goat serum in PBS for 1 h. The cells were subsequently incubated for 45 min with a rabbit anti-O4 antibody (Difco) at a dilution 1:250 in 2% goat serum and then washed three times with PBS. The coverslips were then stained with the secondary antibody (Alexa Fluor 594, goat anti-rabbit immunoglobulin G; Molecular Probes) and Hoechst nuclear stain, washed three times with PBS, and then mounted on slides. Fluorescence analysis was performed with a Nikon Eclipse E800 microscope. Three random fields for each coverslip were selected, and pictures were taken on the 4',6'-diamidino-2-phenylindole (DAPI) and Texas red channels with a digital camera (DS L-1; Nikon). For those strains expressing green fluorescent protein (GFP), the fluorescence isothiocyanate fluorescence was analyzed as well.

Analysis of protein secretion. Bacteria were grown under SPI-1-inducing conditions as described above. The cells were pelleted by centrifugation, and 2 ml of supernatant was collected for each sample. The supernatants were then filtered (0.45-μm pore size), and the proteins were precipitated with 25% trichloroacetic acid by high-speed centrifugation (14,000 × g for 30 min). The pellet was washed in cold acetone and resuspended in PBS. Four independent extractions for each sample were added together to minimize differences in protein recovery from sample to sample. The proteins were then boiled in sodium dodecyl sulfate (SDS) for 5 min, and an aliquot of each sample was separated by SDS-10% polyacrylamide gel electrophoresis (SDS-PAGE).

Animal experiments. Four male Holstein calves, 4 to 5 weeks of age, weighing 45 to 55 kg, were used. They were fed milk replacer twice a day and water ad libitum. The calves were clinically healthy before the experiment and were culture negative for fecal excretion of *Salmonella* serotypes. Detection of *Salmonella* serotypes in fecal swabs was performed by enrichment in tetrathionate broth (Difco) and streaking on brilliant green agar (BBL).

Bovine ligated ileal loop surgery has been described previously (27). In brief, the calves were fasted for 24 h prior to the surgery. Anesthesia was induced with

propofol (PropoFlo; Abbott Laboratories, Chicago, Ill.), followed by placement of an endotracheal tube and maintenance with isoflurane (Isoflo; Abbott Laboratories) for the duration of the experiment. A laparotomy was performed, the ileum was exposed, and loops with lengths ranging from 6 to 9 cm were ligated, leaving 1-cm loops between them. The loops were infected by intraluminal injection of 3 ml of a suspension of either sterile LB broth or *S. enterica* serotype Typhimurium strains in LB broth containing approximately 10⁹ CFU. The loops were returned to the abdominal cavity. Samples for bacteriologic culture were collected at 1 h after infection with a 3.5-mm biopsy punch and incubated in PBS containing 0.1 mg of gentamicin per liter for 90 min. Tissue samples were homogenized in PBS, serially diluted, and plated onto LB agar plates containing appropriate antibiotics for enumeration of CFU. Data on bacterial CFU were normalized to the length of the ligated loop and the number of CFU present in the inoculum prior to statistical analysis.

Ex vivo tissue explants. Uninfected tissue from loops infected with sterile LB broth (see above) was collected with a 3.5-mm biopsy punch and placed on sterile Whatman paper with the mucosal side oriented upward. Invasion of these tissue explants was investigated with a micro-Snapwell system as described previously (7). In brief, circular Plexiglas pieces with a 12-mm diameter and a 3-mm-diameter central hole (Rohm & Haas Co., Philadelphia, Pa.) were washed in 100% ethanol, air dried, and sterilized overnight under UV light. Tissue samples were sandwiched between two Plexiglas pieces and inserted into Costar Snapwell plates (Costar Corning Inc., Acton, Mass.). The luminal side of the tissue sample (containing a surface area of 7 mm²) was infected with *S. enterica* serotype Typhimurium (approximately 10⁷ CFU/well) and incubated for 1 h at 37°C and 5% CO₂ to allow bacterial invasion. One hour after infection, samples were washed three times with 0.5 ml of PBS and incubated with gentamicin for 90 min. Tissue samples were homogenized in PBS, serially diluted, and plated onto LB agar plates containing nalidixic acid (50 μg/ml) for counting of CFU. Data on bacterial CFU recovered from tissue were normalized to bacterial numbers present in the inoculum prior to statistical analysis.

Statistical analysis. For analysis of percentages, the data were transformed logarithmically. Geometric means were determined, and the statistical significance of differences was calculated with parametric tests. A two-tailed Student *t* test was used to determine whether introduction of plasmids into the *sipA sopABDE2* mutant resulted in significant changes in the invasiveness of the resulting strain.

RESULTS

Proteins secreted by *S. enterica* serotype Typhimurium strains. The contribution of effector genes to invasion was assessed by introducing them (*sipA*, *sopA*, *sopB*, *sopD*, and/or *sopE2*), cloned on a low-copy-number plasmid (pWSK29, about six copies per cell), into a *sipA sopABDE2* mutant (ZA21). The strain used by our laboratory to study enteropathogenicity in the calf model, *S. enterica* serotype Typhimurium ATCC 14028, does not carry SopEΦ. Thus, we did not include the *sopE* gene (carried by SopEΦ) in our analysis. Proteins were isolated from culture supernatants and analyzed

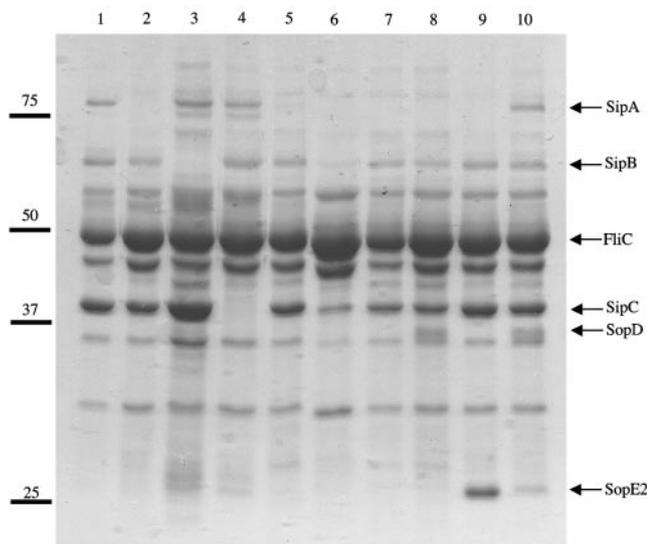

FIG. 1. Analysis of proteins secreted by *S. enterica* serotype Typhimurium into the culture supernatant. Proteins were separated by SDS-PAGE and stained with Coomassie blue. Positions (bars) and molecular weights (10^3) of standard proteins are shown on the left. Lanes: 1, IR715 (wild type); 2, ZA21 (*sipA sopABDE2* mutant); 3, CAS152 (*sipB* mutant); 4, CAS108 (*sipC* mutant); 5, ZA21(pMR29) (*sipA sopABDE2* mutant complemented with *sipA*); 6, ZA21(pMR28) (*sipA sopABDE2* mutant complemented with *sopA*); 7, ZA21(pMR28) (*sipA sopABDE2* mutant complemented with *sopB*); 8, ZA21(pMR15) (*sipA sopABDE2* mutant complemented with *sopD*); 9, ZA21(pMR17) (*sipA sopABDE2* mutant complemented with *sopE2*); 10, ZA21(pMR31) (*sipA sopABDE2* mutant complemented with *sipA sopABDE2*).

by SDS-PAGE to evaluate the secretion of T3SS-1 effectors in the bacterial supernatant (Fig. 1). Bands with apparent sizes of 68 (SipB) and 40 (SipC) kDa were absent only from the culture supernatants of a *sipB* mutant (CAS152) and a *sipC* mutant (CAS108), respectively. The proteins SipB and SipC were secreted at equal levels in ZA21 complemented with various plasmids (pMR15, pMR17, pMR26, pMR29, and pMR31), except in a strain carrying the cloned *sopA* gene (pMR28), in which expression was reduced. A large band (approximately 80 kDa) was visible in culture supernatants of strains IR715 (wild type), CAS152, CAS108, and ZA21(pMR31), suggesting that this band represented SipA. The presence of an approximately 30-kDa band present in culture supernatants of strains ZA21 (pMR17) and ZA21(pMR31) suggested that this protein represented SopE2. Similarly, the presence of a 45-kDa band in culture supernatants of strains ZA21(pMR15) and ZA21 (pMR31) suggested that this band represented SopD. We were not able to visualize the expression of SopB and SopA in culture supernatants of *S. enterica* serotype Typhimurium strain ATCC 14028 by SDS-PAGE.

SipA, SopE2, and SopB contribute to the invasion of non-polarized HT-29 cells. Invasiveness of *S. enterica* serotype Typhimurium strains for the human colon carcinoma cell line HT-29 was determined with nonpolarized cells and a standard gentamicin protection assay. Wild-type *S. enterica* serotype Typhimurium was recovered in 600-fold higher numbers from HT-29 cells than the *sipA sopABDE2* mutant was (Fig. 2). The invasion defect of the *sipA sopABDE2* mutant could be fully restored by introducing the cloned *sipA* and *sopABDE2* genes

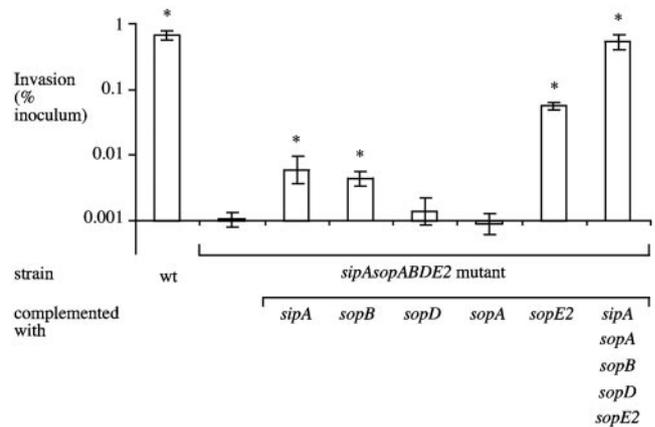

FIG. 2. Invasion of nonpolarized HT-29 cells by *S. enterica* serotype Typhimurium. Data are plotted as geometric means from at least four independent assays (bars) \pm the standard errors. Asterisks indicate that differences between the invasiveness of the *sipA sopABDE2* mutant and that of other strains for HT-29 cells were statistically significant ($P < 0.05$). wt, wild type.

on a plasmid. Introduction of the cloned *sopD* or *sopA* gene did not increase the invasiveness of the *sipA sopABDE2* mutant. However, introduction of the cloned *sipA*, *sopB*, or *sopE2* gene on a plasmid significantly increased the invasiveness of the *sipA sopABDE2* mutant for HT-29 cells ($P < 0.05$). While it has been shown previously that a mutation in *sipA* results in a brief (5-min) delay in the invasion of tissue culture cells (21, 44), this is the first report demonstrating that the *sipA* gene mediates the invasion of human cell lines.

To determine whether introduction of *sipA* expressed from a heterologous promoter and cloned on a low-copy-number plasmid would alter the outcome of an invasion assay, we compared the invasiveness of the *sipA sopABDE2* mutant (ZA21) with that of a *sopABDE2* mutant (ZA20, which carries a chromosomal copy of *sipA*) and with that of derivatives of these strains carrying the cloned *sipA* gene (pMR29). There was no significant difference in invasiveness among strains ZA20, ZA21(pMR29), and ZA20(pMR29), suggesting that both the chromosomal and plasmid-encoded copies of *sipA* similarly effected entry of *S. enterica* serotype Typhimurium into HT-29 cells (Fig. 3). ZA20, ZA21(pMR29), and ZA20(pMR29) were recovered in significantly higher numbers ($P < 0.01$) from HT-29 cells than from either the *sipA sopABDE2* mutant (ZA21) or strain AJB75, which carries a defective form of T3SS-1 because of a mutation in *invA*. There was no significant difference in the invasiveness for HT-29 cells of strains ZA21 (*sipA sopABDE2*) and AJB75 (*invA*). Strains AJB75, ZA20, ZA21, ZA21(pMR29), and ZA20(pMR29) were recovered in significantly lower numbers from HT-29 cells than wild-type *S. enterica* serotype Typhimurium (IR715) was.

To ensure that the results of the gentamicin protection assay were not influenced by differences between strains in the formation of antibiotic-resistant aggregates of extracellular bacteria, we analyzed extracellular bacteria by fluorescence microscopy. In a first experiment, HT-29 cells infected with the wild type (IR715) carrying a plasmid encoding GFP (pGFP-UV) were treated with gentamicin for 90 min and then fixed without being permeabilized. Extracellular bacteria were la-

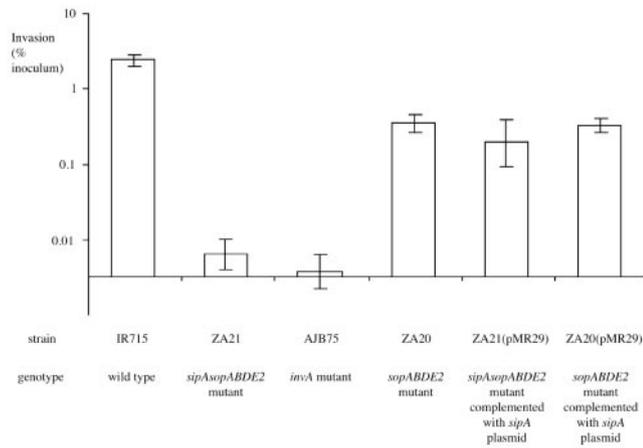

FIG. 3. Invasion of nonpolarized HT-29 cells by *S. enterica* serotype Typhimurium. Data are plotted as geometric means from at least four independent assays (bars) \pm the standard errors.

beled with anti-lipopolysaccharide (LPS) antibodies (rabbit anti-O4 and goat anti-rabbit Alexa Fluor 594; red fluorescence) but did not show green fluorescence, presumably because GFP was not stable for 90 min after extracellular bacteria were killed by addition of gentamicin. Bacteria exhibiting green fluorescence were not labeled by the anti-LPS antibody, suggesting an intracellular location. The experiment shown in Fig. 2 was then repeated, and extracellular bacteria were fluorescently labeled with anti-LPS antibody as described above. No differences in the appearance (i.e., clumping) or numbers of extracellular bacteria were noted when three microscopic fields were examined for each strain (data not shown). These data showed that the 600-fold difference in the numbers of viable bacteria recovered from gentamicin protection assays with HT-29 cells (Fig. 2) could not be explained by the presence of different numbers of extracellular bacteria, suggesting that the differences were due to different numbers of intracellular bacteria.

SopE2 contributes to invasion of nonpolarized T84 cells. We studied the invasiveness of *S. enterica* serotype Typhimurium strains for the human colon carcinoma cell line T84. Wild-type *S. enterica* serotype Typhimurium was recovered in approximately 100-fold higher numbers from nonpolarized T84 cells than the *sipA sopABDE2* mutant was (Fig. 4). The invasion defect of the *sipA sopABDE2* mutant could be fully restored by introducing the cloned *sipA sopABDE2* genes on a plasmid. Introduction of the cloned *sopE2* gene but not introduction of the cloned *sipA*, *sopB*, *sopD*, or *sopA* gene significantly increased the invasiveness of the *sipA sopABDE2* mutant for nonpolarized T84 cells. Comparison of results obtained with nonpolarized HT-29 cells (Fig. 2) and nonpolarized T84 cells (Fig. 4) suggested that differences between human colon carcinoma cell lines significantly influence the mechanisms available for *S. enterica* serotype Typhimurium entry into host cells.

SopA, SopD, SopE2, and SopB contribute to invasion of polarized T84 cells. Polarization of epithelial cell lines changes the distribution of factors required for *S. enterica* serotype Typhimurium invasion (4, 5). We reasoned that polarized colon carcinoma cells may more closely resemble epithelial cells in the intestinal mucosa with regard to actin architecture and

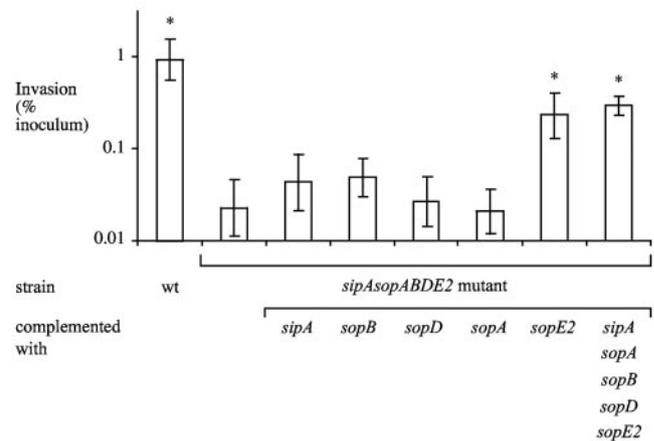

FIG. 4. Invasion of nonpolarized T84 cells by *S. enterica* serotype Typhimurium. Data are plotted as geometric means from at least four independent assays (bars) \pm the standard errors. Asterisks indicate that differences between the invasiveness of the *sipA sopABDE2* mutant and that of other strains for T84 cells were statistically significant ($P < 0.05$). wt, wild type.

the presence in their apical membrane of factors required for invasion and may thus be a better model for identifying genes that contribute to mucosal invasion. Wild-type *S. enterica* serotype Typhimurium was recovered in approximately 100-fold higher numbers from polarized T84 cells than the *sipA sopABDE2* mutant was. The invasion defect of the *sipA sopABDE2* mutant could be complemented by introducing the cloned *sipA sopABDE2* genes on a plasmid (Fig. 5B). Introduction of the cloned *sopE2*, *sopB*, *sopD*, or *sopA* gene significantly increased the invasiveness of the *sipA sopABDE2* mutant for polarized T84 cells (Fig. 5B). This is the first report showing that *sopD* and *sopA* are involved in the invasion of host cells by *S. enterica* serotype Typhimurium. Our data demonstrate that polarization of epithelial cells dramatically alters the requirements for *S. enterica* serotype Typhimurium invasion, thereby providing a possible explanation for why the contribution of SopD and SopA to invasion has not previously been observed in studies with nonpolarized cells.

SipA and SopB synergistically promote invasion and loss of TER. Introduction of the cloned *sipA* gene did not significantly increase the invasiveness of the *sipA sopABDE2* mutant for polarized T84 cells (Fig. 5B). However, introduction of a plasmid carrying *sipA* and *sopB* significantly increased the invasiveness of the *sipA sopABDE2* mutant for polarized T84 cells compared to the introduction of each individual effector gene (Fig. 6A). These data suggested that SipA acts in concert with SopB during the invasion of polarized T84 cells. A synergism between *sipA* and *sopB* was also observed during the invasion of nonpolarized HT-29 cells. Complementation of the *sipA sopABDE2* mutant with a plasmid carrying *sopB* and *sipA* resulted in 100-fold greater invasion of nonpolarized HT-29 cells than complementation with either *sipA* or *sopB* alone (data not shown). In summary, our data provide evidence for contributions of *sipA*, *sopE2*, *sopB*, *sopD*, and *sopA* to the invasion of colon carcinoma cells.

Infection of polarized T84 cells with wild-type *S. enterica* serotype Typhimurium caused a rapid loss of TER compared

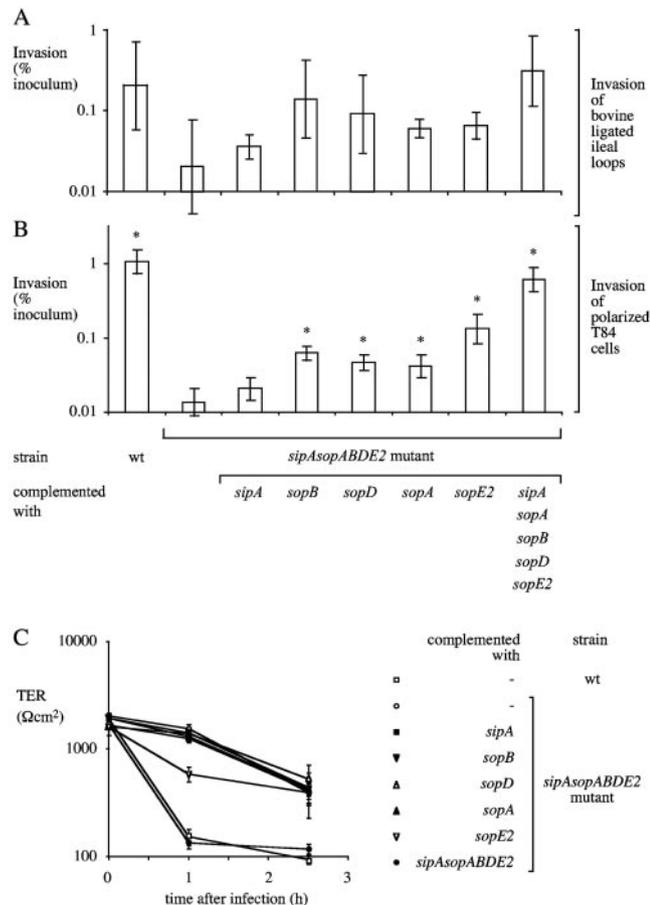

FIG. 5. Invasion of *S. enterica* serotype Typhimurium in bovine ligated ileal loops (A) and polarized T84 colon carcinoma cells (B). Data are plotted as geometric means from at least four independent assays (bars) \pm the standard errors. Asterisks indicate that differences between the invasiveness of the *sipA sopABDE2* mutant and that of other strains for polarized T84 cells were statistically significant ($P < 0.05$). (C) TER during invasion of polarized T84 cells. Data are shown as means \pm the standard deviation. wt, wild type.

to infection with the *sipA sopABDE2* mutant (Fig. 5C and 6B). Similarly, introduction of a plasmid containing *sipA* and *sopB* (Fig. 6B) or a plasmid containing all five effector genes (Fig. 5C) into the *sipA sopABDE2* mutant resulted in rapid loss of TER. Introduction of individual effector genes into the *sipA sopABDE2* mutant resulted in no decrease (in the case of *sipA*, *sopB*, *sopD*, or *sopA*) or only a small decrease (in the case of *sopE2*) in TER (Fig. 5C).

Assays with bovine intestinal tissue are less well suited for assessing the invasiveness of *S. enterica* serotype Typhimurium than tissue culture models are. To assess the contribution of effector genes to invasion of the bovine ileal mucosa, ligated ileal loops were infected with bacterial strains and collected 1 h after infection. Bacterial numbers recovered from biopsy punches of each loop were determined after tissue had been incubated with gentamicin to kill extracellular bacteria. Overall, the relative contribution of effector genes to the invasion of polarized T84 cells (Fig. 5B) was similar to that seen in bovine ligated ileal loops (Fig. 5A). Wild-type *S. enterica* serotype Typhimurium was recovered in higher numbers from the ileal

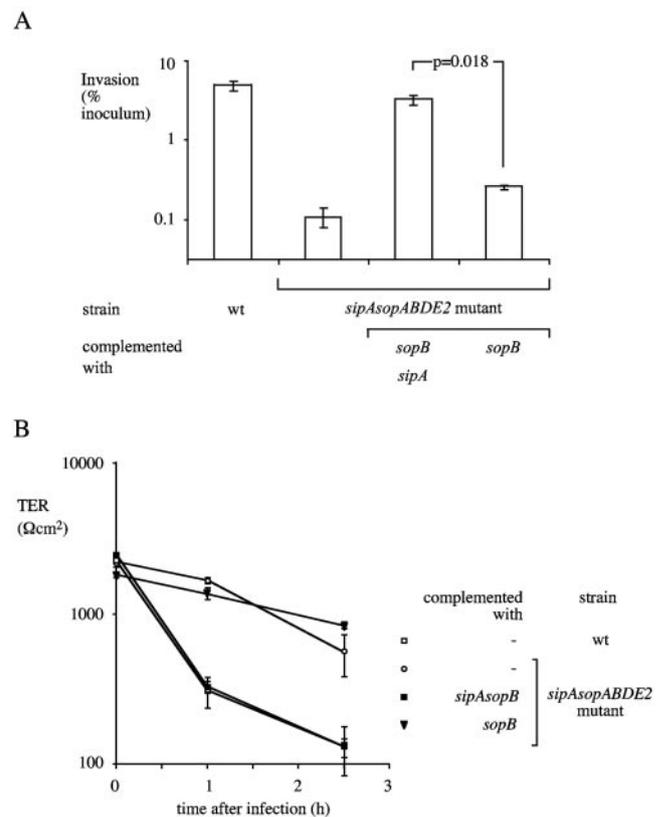

FIG. 6. Invasion of polarized T84 cells by *S. enterica* serotype Typhimurium (A). Data are plotted as geometric means from CFU recovered from three different wells (bars) \pm the standard errors. (B) TER during invasion of polarized T84 cells. Data are shown as means \pm the standard deviation. wt, wild type.

mucosa than the *sipA sopABDE2* mutant was (Fig. 5A). This invasion defect was complemented by introducing the cloned *sipA sopABDE2* genes into the *sipA sopABDE2* mutant on a plasmid ($P < 0.05$). The *sipA sopABDE2* mutant complemented with either *sipA*, *sopA*, *sopB*, *sopD*, or *sopE2* invaded at higher levels than the *sipA sopABDE2* mutant did but at lower levels than wild-type *S. enterica* serotype Typhimurium did. These differences were not statistically significant, which was mainly due to two technical difficulties. The first limitation was a large variation between the numbers of bacteria recovered from the mucosae of different animals. The second limitation was the fact that the wild type was only recovered in about 10-fold higher numbers from tissue than the *sipA sopABDE2* mutant was, leaving a relatively small window for detecting the contributions of individual effector genes.

Much larger differences between the wild type and the *sipA sopABDE2* mutant were observed when invasion was studied in tissue culture (i.e., IR715 was recovered in 50- to 600-fold higher numbers than ZA21 was) (Fig. 2, 4, and 5B) than when it was studied in bovine ligated loops (i.e., IR715 was recovered in 10-fold higher numbers than ZA21 was) (Fig. 5A). It is possible that differences in the invasiveness of the wild type (IR715) relative to that of the *sipA sopABDE2* mutant (ZA21) are due to different growth conditions encountered in tissue culture compared to the milieu of the ligated ileal loop. To test

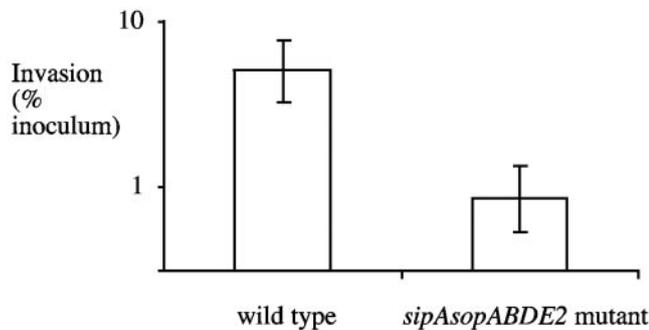

FIG. 7. Invasion of bovine small intestinal tissue explants by *S. enterica* serotype Typhimurium. Data are plotted as geometric means from two independent assays (bars) \pm the standard errors.

this possibility, we performed invasion assays with bovine ileal biopsy tissue explants under conditions used in tissue culture invasion assays. Tissue samples were sandwiched between Plexiglas inserts and inserted into Snapwell plates to limit bacterial exposure to the mucosal surface. Importantly, this method allowed us to perform invasion assays with bovine tissue under conditions identical to those used for infection of polarized T84 cells. In contrast to invasion assays performed with polarized T84 cells (Fig. 5C), the TER remained constant in invasion assays performed with bovine tissue explants (data not shown). Wild-type *S. enterica* serotype Typhimurium was recovered in approximately sixfold higher numbers from the ileal mucosa than the *sipA sopABDE2* mutant was (Fig. 7). The results in Fig. 7 show that the invasiveness of the wild type (IR715) relative to that of the *sipA sopABDE2* mutant in tissue explants was much closer to that observed in ligated ileal loops (10-fold higher than that of the *sipA sopABDE2* mutant) than to that observed in tissue culture (50- to 600-fold higher than that of the *sipA sopABDE2* mutant), even though the explants and polarized T84 cells were infected under similar conditions. This difference in the invasiveness of *S. enterica* serotype Typhimurium for bovine tissue compared to that for human cell lines may result from differences in the mechanism of invasion (i.e., invasion efficiency may differ between tissue and tissue culture) or from differences in bacterial recovery (i.e., tissue may provide better protection from gentamicin-mediated killing). However, our data do indicate that the differences between explants and polarized T84 cells were not due to differences in culture conditions.

DISCUSSION

The goal of this study was to determine whether all of the T3SS-1 effectors previously implicated in eliciting fluid accumulation and inflammation in the calf model of enterocolitis (41) are also required for invasion of epithelial cells in vitro. Previous studies that relied heavily on an analysis of bacterial invasion of nonpolarized cell lines by strains lacking individual effectors faced limitations due to genetic redundancy in bacterial invasion mechanisms and the absence of a brush border on host cells. In this study we used an alternate approach of complementing a strain lacking all of the effector genes required to elicit fluid accumulation and inflammation in the calf

(a *sipA sopABDE2* mutant) by introducing individual effector genes cloned on a low-copy-number plasmid (pWSK29).

Mutational analysis has shown that wild-type *S. enterica* serotype Typhimurium is 2 times more invasive for nonpolarized human colon carcinoma (Int-407) cells (42) and 10 times more invasive for hamster (CHO) cells and human larynx carcinoma (HeLa) cells (19) than a *sopB* mutant is. Consistent with these reports, we show that introduction of the cloned *sopB* gene into the *sipA sopABDE2* mutant increased its invasiveness for nonpolarized human colon carcinoma (HT-29) cells fourfold (Fig. 2). Wild-type *S. enterica* serotype Typhimurium has been shown to be 1.2 times more invasive for nonpolarized simian kidney fibroblast (COS7) cells (28) and fourfold more invasive for HeLa cells (1) than a *sopE2* mutant is. Our data demonstrate that introduction of the cloned *sopE2* gene into the *sipA sopABDE2* mutant increased its invasiveness 50-fold for HT-29 cells (Fig. 2) and 10-fold for T84 cells (Fig. 5). Wild-type *S. enterica* serotype Typhimurium has been shown to be as invasive as a *sipA* mutant for canine kidney (MDCK) cells when bacteria are recovered 15 min after infection or at subsequent time points (21). In contrast, we show that introduction of the cloned *sipA* gene into the *sipA sopABDE2* mutant increased its invasiveness for HT-29 cells sixfold (Fig. 2). Thus, the contribution of *sipA* and *sopE2* to the invasion of nonpolarized cells could be demonstrated more clearly by complementation of a *sipA sopABDE2* mutant than by previous characterization of strains in which one gene was inactivated.

Studying invasion of tissue was complicated by the fact that differences in the invasiveness of the strains tested were small and difficult to demonstrate given the relatively large variation observed during animals experiments. Thus, the bovine ligated ileal loop model and the bovine tissue explant model are less well suited for analyzing bacterial invasion than tissue culture models are. However, analysis of *S. enterica* serotype Typhimurium interaction with the bovine mucosa can provide insights into aspects of host-pathogen interaction that appear not to be modeled in tissue culture. For example, we did not observe loss of TER in infected tissue explants while polarized T84 monolayers rapidly lost their TER during invasion.

Our data provide evidence for a synergistic action between SopB and SipA during the invasion of HT-29 and T84 cells (Fig. 6A). A synergistic action of T3SS-1 effectors during host cell invasion has previously been reported for SopB, SopE, and SopE2 (26, 42). Wild-type *S. enterica* serotype Typhimurium was shown to be 100-fold more invasive for nonpolarized COS7 cells than a *sopB sopE sopE2* mutant and 600-fold more invasive than a strain carrying a defective form of T3SS-1 (*invG* mutant) (26). These and similar results obtained with Int-407 cells led to the conclusion that SopB, SopE, and SopE2 are the only effectors required for invasion of epithelial cells (26, 42). Although this conclusion may be correct for nonpolarized COS7 and Int-407 cells, our data show that different combinations of effectors contributed to the invasion of nonpolarized T84 and HT-29 cells (Table 3). While SopB, SipA, and SopE2 enhanced the invasiveness of the *sipA sopABDE2* mutant for nonpolarized HT-29 cells (Fig. 2), only introduction of the cloned *sopE2* gene significantly enhanced the invasiveness of the *sipA sopABDE2* mutant for nonpolarized T84 cells (Fig. 4). Thus, caution should be taken in generalizing results obtained with individual nonpolarized cell lines.

TABLE 3. Contribution of T3SS-1 effectors to invasion of different cell lines

Cell line and culture condition	<i>S. enterica</i> serotype Typhimurium strain	Effector(s) contributing to invasion	Reference(s)
Polarized T84	ATCC 14028	SopB, SopD, SopA, SopE2, SipA ^a	This study
Nonpolarized T84	ATCC 14028	SopE2	This study
Nonpolarized HT29	ATCC 14028	SipA, SopB, SopE2	This study
Nonpolarized Int407	SL1344	SopB, SopE, SopE2	42
Nonpolarized HeLa	ATCC 14028, F98	SopB, SopE2	1, 19
Nonpolarized CHO	ATCC 14028	SopB	19
Nonpolarized COS7	SL1344	SopB, SopE, SopE2	26, 42

^a A contribution of SipA can only be detected in the presence of SopB.

Perhaps the most significant result of this study is that the contribution of some T3SS-1 effectors to invasion was only apparent when polarized epithelial cells were used. This finding is highly relevant because polarized human colon carcinoma cells are thought to resemble epithelial cells encountered by *S. enterica* serotype Typhimurium in the intestinal mucosa more closely than other cell culture models do. Comparison of the general pattern of invasion observed in bovine ligated ileal loops with that observed in polarized T84 cells supported this view (Fig. 5A and B). Polarization of cells has previously been shown to affect host cell signaling pathways activated by *S. enterica* serotype Typhimurium during bacterial entry. While *S. enterica* serotype Typhimurium activates the GTPases Rac1 and CDC42 when entering nonpolarized MDCK cells, only Rac1 is activated when the bacterium invades the apical membrane of polarized MDCK cells (4). A likely explanation for this observation is that SopE, a nucleotide exchange factor for Rac1 (16), acts locally at sites underlying bacterial contact and that Rac1 is more abundant in apical membrane compartments than CDC42 is (4).

Importantly, previous studies with nonpolarized cells did not provide evidence for a contribution of SopA and SopD to bacterial invasion (26, 36). In contrast, our data show that the *sopD* and *sopA* genes contributed to the invasion of polarized but not nonpolarized T84 cells (Fig. 5B). This is the first report implicating these effectors in bacterial entry into mammalian cells and suggests that at least six T3SS-1 effectors, including SipA, SopA, SopB, SopD, SopE, and SopE2, are involved in epithelial invasion (Table 3). It could be speculated that SopA and SopD may only be required during invasion of the brush border of an epithelial cell. However, it is difficult to study the underlying mechanisms because the cellular targets of SopA and SopD have not been identified.

ACKNOWLEDGMENTS

We thank Anna Sapone and Alessio Fasano for help in setting up micro-Snapwell invasion assays and Renée M. Tsolis, Josely Figueiredo, Jairo Nunes, Tamara Gull, Carlos Rossetti, and Andrea Humphries for assistance during calf surgery.
