(Received 6 July 2016; published 7 October 2016)

We report results of a search for oscillations involving a light sterile neutrino over distances of 1.04 and 735 km in a  $\nu_\mu$ -dominated beam with a peak energy of 3 GeV. The data, from an exposure of  $10.56 \times 10^{20}$  protons on target, are analyzed using a phenomenological model with one sterile neutrino. We constrain the mixing parameters  $\theta_{24}$  and  $\Delta m_{41}^2$  and set limits on parameters of the four-dimensional Pontecorvo-Maki-Nakagawa-Sakata matrix,  $|U_{\mu 4}|^2$  and  $|U_{e 4}|^2$ , under the assumption that mixing between  $\nu_e$  and  $\nu_s$  is negligible ( $|U_{e 4}|^2 = 0$ ). No evidence for  $\nu_\mu \rightarrow \nu_s$  transitions is found and we set a world-leading limit on  $\theta_{24}$  for values of  $\Delta m_{41}^2 \lesssim 1 \text{ eV}^2$ .

DOI: 10.1103/PhysRevLett.117.151803

Studies of neutrinos and antineutrinos produced in the Sun, the atmosphere, and by reactors and accelerators [1] have established that neutrinos have mass and that the weak-interaction flavor eigenstates  $\nu_\ell$  ( $\ell = e, \mu, \tau$ ) are related to the mass eigenstates  $\nu_i$  ( $i = 1, 2, 3$ ) by a mixing matrix  $U$ :

$$|\nu_\ell\rangle = \sum_i U_{\ell i} |\nu_i\rangle. \quad (1)$$

Measurements of the shape of the Z-boson resonance [2] show that there are three active neutrino flavors with masses less than  $m_Z/2$ . The standard picture of neutrino mixing therefore assumes  $U$  is a  $3 \times 3$  matrix, the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) matrix [3–5], that relates the flavor states to three neutrino mass states  $m_1, m_2$ , and  $m_3$ . The matrix is commonly parametrized using three mixing angles,  $\theta_{12}, \theta_{23}$ , and  $\theta_{13}$ , and a charge-parity violating phase  $\delta$  [6]. The three angles and the two mass splittings  $\Delta m_{21}^2 = m_2^2 - m_1^2$  and  $|\Delta m_{32}^2| = |m_3^2 - m_2^2|$  have been measured in multiple experiments [1].

The three-flavor model of neutrino mixing provides an excellent description of most, but not all, neutrino data. In particular, the Liquid Scintillator Neutrino Detector (LSND) observed a  $3.8\sigma$  excess consistent with  $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$  oscillations driven by a mass splitting  $0.2 \leq \Delta m^2 \leq 10 \text{ eV}^2$  that is incompatible with  $\Delta m_{21}^2$  or  $\Delta m_{32}^2$  [7]. The MiniBooNE experiment searched for oscillations in the same range of mass splittings using beams of  $\nu_\mu$  and  $\bar{\nu}_\mu$  and found  $3.4\sigma$  and  $2.8\sigma$  excesses of  $\nu_e$  and  $\bar{\nu}_e$ , respectively [8].

Many experiments have measured  $\bar{\nu}_e$  fluxes from reactors at short baselines of 10–1000 m. A recent calculation [9,10] predicts a flux that is about 3% larger than previously assumed. The data display a deficit with respect to that prediction, the “reactor anomaly,” which can be interpreted as  $\bar{\nu}_e$  disappearance due to oscillations with  $\Delta m^2 \gtrsim 0.1 \text{ eV}^2$  [11]. Finally, a deficit of  $\nu_e$  has been observed from the gallium calibration sources of SAGE and GALLEX [12,13], which, when interpreted as oscillations, is consistent with the  $\Delta m^2$  range favored by the reactor anomaly.

The anomalous oscillation signals described above may potentially be reconciled with data supporting the three-flavor oscillation picture by the addition of one or more

sterile neutrinos that do not experience the weak interaction, but which mix with the active neutrinos [14]. Since neutrinos have mass, sterile states may naturally arise from extensions to the standard model [15]. In this Letter, we test a phenomenological model in which the PMNS matrix is extended by the addition of a fourth neutrino mass eigenstate  $\nu_4$  and a single sterile flavor state  $\nu_s$ . This “3 + 1” phenomenological model introduces three new mixing angles  $\theta_{14}, \theta_{24}$ , and  $\theta_{34}$ , and two additional phases  $\delta_{14}$  and  $\delta_{24}$  when parametrized as in Ref. [6]. In this nomenclature the PMNS phase  $\delta \equiv \delta_{13}$  and all  $\delta_{ij}$ -dependent terms appear multiplied by the corresponding  $\sin\theta_{ij}$  in  $U$ . In the following discussion we denote individual elements of  $U$  as  $U_{li}$  with  $l = e, \mu, \tau, s$  and  $i = 1, \dots, 4$ . We also write  $c_{ij} = \cos\theta_{ij}$ ,  $s_{ij} = \sin\theta_{ij}$ , and  $\Delta_{ji} = (\Delta m_{ji}^2 L/4E_\nu)$ , where  $\Delta m_{ji}^2 \equiv m_j^2 - m_i^2$ ,  $L$  is the distance traveled by the neutrino, and  $E_\nu$  is the neutrino energy.

The MiniBooNE and LSND experiments were conducted at  $L/E_\nu \sim 1 \text{ km/GeV}$ , a parameter space in which  $\sin^2 \Delta_{32} \sim 10^{-5}$  and  $\sin^2 \Delta_{21} \sim 10^{-8}$ , rendering oscillations due to  $\Delta m_{32}^2$  and  $\Delta m_{21}^2$  negligible. In this case, and assuming  $|\Delta m_{41}^2| \gg |\Delta m_{32}^2| > |\Delta m_{21}^2|$ , the  $\nu_e$  appearance probability is

$$P(\nu_\mu \rightarrow \nu_e) = 4|U_{\mu 4}|^2|U_{e 4}|^2 \sin^2 \Delta_{41}, \quad (2)$$

where  $|U_{\mu 4}| = c_{14}s_{24}$  and  $|U_{e 4}| = s_{14}$ . Reactor experiments study  $\bar{\nu}_e \rightarrow \bar{\nu}_e$  and have placed stringent limits on  $\theta_{14}$  [16,17].

MINOS measures neutrino oscillations using  $\nu_\mu$  charged-current (CC) and neutral-current (NC) interactions in a far detector (FD) and a near detector (ND) separated by 734 km [18,19]. The neutrinos are produced by directing protons with energies of 120 GeV from the Fermilab Main Injector onto a graphite target, located 1.04 km upstream of the ND, producing  $\pi$  and  $K$  mesons. These mesons are focused by magnetic horns before decaying in a 675 m long tunnel to produce predominantly muon-type neutrinos [20]. The ranges of  $L/E$  probed by the two MINOS detectors are shown in Fig. 1. Disappearance of  $\nu_\mu$  occurs with a probability

FIG. 1. Muon neutrino oscillation probabilities as a function of  $L/E$ , where  $L$  is the distance traveled by the neutrinos, and  $E$  is the reconstructed neutrino energy (top horizontal axis of each panel), for three different values of  $\Delta m_{41}^2$ , with  $\theta_{14} = 0.15$ ,  $\theta_{24} = 0.2$ ,  $\theta_{34} = 0.5$ , and values of  $\Delta m_{31}^2$ ,  $\Delta m_{21}^2$ ,  $\theta_{12}$ ,  $\theta_{23}$ , and  $\theta_{13}$  from Ref. [1]. The dip in  $P(\nu_\mu \rightarrow \nu_\mu)$  at 500 km/GeV is due to oscillations driven by  $\Delta m_{31}^2$ . As  $L/E$  increases, the various oscillation probabilities become similar and the lines overlap. The gray bands indicate the regions of reconstructed energy where CC  $\nu_\mu$  interactions (top panel) and NC interactions (bottom panel) are observed in the two detectors.

$$P(\nu_\mu \rightarrow \nu_\mu) = 1 - 4 \sum_{i=1}^4 \sum_{j>i}^4 |U_{\mu i}|^2 |U_{\mu j}|^2 \sin^2 \Delta_{ji}. \quad (3)$$

In the analysis presented in this Letter, we use the exact oscillation probability to extract limits on the parameters. In the following discussion of the phenomenology, for simplicity we only show leading terms.

Terms in  $\Delta_{21}$  are negligible, and we can approximate  $\Delta m_{32}^2 \approx \Delta m_{31}^2$ . In the limit  $\Delta m_{41}^2 \gg \Delta m_{31}^2$  we can also approximate  $\Delta m_{43}^2 \approx \Delta m_{42}^2 \approx \Delta m_{41}^2$  and expand the oscillation probability to second order in the small terms  $s_{13}$ ,  $s_{14}$ ,  $s_{24}$  and  $\cos 2\theta_{23}$ , yielding

$$P(\nu_\mu \rightarrow \nu_\mu) \approx 1 - \sin^2 2\theta_{23} \cos 2\theta_{24} \sin^2 \Delta_{31} - \sin^2 2\theta_{24} \sin^2 \Delta_{41}. \quad (4)$$

Thus, mixing with sterile neutrinos in the MINOS CC  $\nu_\mu$  sample is controlled by  $\theta_{24}$  and would be seen as a depletion of events for  $\Delta_{41} \gtrsim \pi/2$ , as shown in the top panel of Fig. 1.

For  $10^{-3} \lesssim \Delta m_{41}^2 \lesssim 0.1 \text{ eV}^2$  an energy-dependent depletion would be observed at the FD with no effect at the ND. The  $\Delta m_{41}^2 = 0.05 \text{ eV}^2$  curve in the top panel of Fig. 1 shows an example of this behavior. As  $\Delta m_{41}^2$  increases toward  $1 \text{ eV}^2$  we have  $\Delta_{41} \gg \pi/2$  at the FD. In this case—the fast-oscillation regime—an energy-independent reduction in the event rate would be observed, since  $\sin^2 \Delta_{41} \rightarrow 1/2$  when the finite energy resolution of the detectors is considered. The  $\Delta m_{41}^2 = 0.50 \text{ eV}^2$  curve in the top panel of Fig. 1 shows an example of fast oscillations. For  $\Delta m_{41}^2 \gtrsim 1 \text{ eV}^2$  an additional energy-dependent depletion of  $\nu_\mu$  would be seen at the ND, with the energy of maximum oscillation increasing with  $\Delta m_{41}^2$ . An example of these ND oscillations is shown by the  $\Delta m_{41}^2 = 5.00 \text{ eV}^2$  curve in the top panel of Fig. 1. For  $\Delta m_{41}^2 \gtrsim 100 \text{ eV}^2$  fast oscillations occur at both detectors.

MINOS is also sensitive to sterile neutrinos via the disappearance of NC events [21–23], as shown in the bottom panel of Fig. 1, which would occur with a probability

$$1 - P(\nu_\mu \rightarrow \nu_s) \approx 1 - c_{14}^4 c_{34}^2 \sin^2 2\theta_{24} \sin^2 \Delta_{41} - A \sin^2 \Delta_{31} + B \sin 2\Delta_{31}. \quad (5)$$

The terms  $A$  and  $B$  are functions of the mixing angles and phases. To first order,  $A = s_{34}^2 \sin^2 2\theta_{23}$  and  $B = \frac{1}{2} \sin \delta_{24} s_{24} \sin 2\theta_{34} \sin 2\theta_{23}$ . The NC sample is therefore sensitive to  $\theta_{34}$  and  $\delta_{24}$  in addition to  $\theta_{24}$ , although that sensitivity is limited by poor neutrino-energy resolution (due to the undetected outgoing neutrino), a lower event rate due to cross sections, and  $\nu_\mu$  and  $\nu_e$  CC backgrounds.

The MINOS apparatus and NuMI beam have been described in detail elsewhere [20,24]. We analyze an exposure of  $10.56 \times 10^{20}$  protons on target (POT) used to produce a  $\nu_\mu$ -dominated beam with a peak energy of 3 GeV. The detectors are magnetized steel-scintillator, tracking-sampling calorimeters that utilize an average field of 1.3 T to measure the charge and momentum of muons. The energy of hadronic showers is measured using calorimetry. In the case of CC  $\nu_\mu$  interactions, this is combined with topological information through a  $k$ -nearest-neighbor algorithm [25].

A sample of NC-enhanced events is isolated by searching for interactions that induce activity spread over fewer than 47 steel-scintillator planes. Events with a reconstructed track are required to penetrate no more than five detector planes beyond the end of the hadronic shower. Additional selection requirements are imposed in the ND to remove cases in which the reconstruction program was confused by multiple coincident events. The selected NC sample in the ND has an efficiency of 79.9% and a purity of 58.9%, both estimated from Monte Carlo (MC) simulation. The background is composed of 86.9% CC  $\nu_\mu$  interactions

and 13.1% CC  $\nu_e$  interactions. At the FD, assuming standard three-flavor oscillations, the efficiency of the sample is 87.6% and the purity is 61.3%, with the backgrounds comprising 73.8% CC  $\nu_\mu$  interactions, 21.6% CC  $\nu_e$  interactions, and 4.6% CC  $\nu_\tau$  interactions. A lower bound on the energy of the incident neutrino is estimated from the energy of the hadronic recoil system, with a mean resolution of 41.7% on the energy of the recoil system in the FD.

We isolate a sample of CC  $\nu_\mu$  ( $\nu_\mu N \rightarrow \mu X$ ) events by searching for interactions inside our detectors with a single outgoing  $\mu$  track and possible hadronic activity from the recoil system  $X$ . We discriminate between CC and NC events by combining four topological variables describing track properties into a single discriminant variable, using a  $k$ -nearest-neighbor algorithm [26]. Events are required to have failed the NC selection procedure to be included in the CC  $\nu_\mu$  sample. In the ND, the selected CC sample has an efficiency of 53.9% and a purity of 98.7%, both estimated from a MC simulation. At the FD, assuming three-flavor oscillations, the corresponding efficiency is 84.6% and the purity is 99.1%. The neutrino energy is reconstructed by summing the energies of the muon and hadronic showers, with a mean resolution of 17.3% in the FD.

MINOS oscillation analyses have traditionally used the CC and NC neutrino energy spectra measured by the ND to predict the spectra at the FD as a function of oscillation parameters [27]. However, the sterile oscillation parameter space to which MINOS is sensitive stretches over the range  $10^{-3} \lesssim \Delta m^2 \lesssim 10^2 \text{ eV}^2$ , which could cause oscillations to impact both detectors [28]. Therefore, instead of using the ND data to predict the FD energy spectra, we analyze the ratio of energy spectra observed in the FD to those observed in the ND. This FD-to-ND ratio is analyzed for both CC  $\nu_\mu$  and NC events, as shown in Fig. 2. Aside from the overall difference in the number of events (caused by the distance between the detectors, their different masses and efficiencies, and the beam divergence) the main effect is the energy-dependent suppression of events at the FD caused by oscillations driven by  $\Delta m_{32}^2$ . Our analysis searches for modulations on top of that oscillation pattern, caused by the sterile sector, by minimizing the  $\chi^2$  as a function of the oscillation parameters:

$$\chi_{\text{CC,NC}}^2 = \sum_{m=1}^N \sum_{n=1}^N (x_m - \mu_m)(V^{-1})_{mn}(x_n - \mu_n) + \text{const.} \quad (6)$$

Here, we denote the measured FD-to-ND ratio as  $x_m$ , where  $m = 1, \dots, N$  labels  $N$  energy bins between 0 and 40 GeV. The predicted ratio is denoted  $\mu_m$ . The dependence of  $\mu_m$  on the oscillation parameters is taken from a MC simulation that includes the full range of experimental effects, and uses an exact form of all oscillation probabilities in vacuum with

FIG. 2. The ratios of the energy spectra in the far detector to those in the near detector, shown for the CC  $\nu_\mu$  (top) and NC (bottom) samples. The solid lines represent the predicted ratios from fits to the standard three-flavor oscillation model and to the 3 + 1 sterile neutrino model.

no approximations. In Eq. (6),  $V$  is an  $N \times N$  covariance matrix expressing the combined statistical and systematic uncertainty on  $\vec{\mu}$ . For very high  $\Delta m_{41}^2 \gtrsim 50 \text{ eV}^2$ , both detectors are in the fast-oscillation limit and the only sensitivity comes from the overall rate measured in one of the two detectors. To account for the uncertainty on the overall rate we add a term  $\chi_{\text{rate}}^2 = [(X - M)^2 / \sigma_M^2]$ , where  $X$  and  $M$  are the total number of ND events measured and simulated, respectively, and  $\sigma_M$  is the uncertainty on  $M$ , which is conservatively assigned a value of 50%, reflecting the fact that most measurements of neutrino fluxes and cross sections assume only three neutrino flavors.

We fit for  $\theta_{23}$ ,  $\theta_{24}$ ,  $\theta_{34}$ ,  $\Delta m_{32}^2$ , and  $\Delta m_{41}^2$ , and hold all other parameters fixed. We set  $\sin^2 \theta_{12} = 0.307$  and  $\Delta m_{21}^2 = 7.54 \times 10^{-5} \text{ eV}^2$  based on a global fit to neutrino data [29], and  $\sin^2 \theta_{13} = 0.022$  based on a weighted average of recent results from reactor experiments [30–32]. An analysis of solar and reactor neutrino data yields the constraint  $\sin^2 \theta_{14} = |U_{e4}|^2 < 0.041$  at 90% CL [33], which is small enough to have a negligible effect on this analysis, so we set  $\theta_{14} = 0$ . This analysis has negligible sensitivity to  $\delta_{13}$  and  $\delta_{14}$ , and minimal sensitivity to  $\delta_{24}$ ; hence, all are set to zero. The impact of including the matter potential in the oscillation probability was investigated and found to have a negligible effect. The neutrino path length between the meson decay point and the ND was taken into account in the computation of oscillation probabilities.

Figure 2 shows a good agreement between the measured FD-to-ND ratios and those predicted using a three-flavor

hypothesis. No significant distortions indicative of sterile neutrinos are observed. The predicted ratios include both statistical and systematic uncertainties that are incorporated into Eq. (6) via a covariance matrix,

$$V = V_{\text{stat}} + V_{\text{norm}} + V_{\text{acc}} + V_{\text{NC}} + V_{\text{other}}, \quad (7)$$

where the terms account for the various sources of uncertainty. Figure 3 shows the effects that the sources of systematic uncertainty have on the sensitivity of the sterile neutrino search. We describe each source of uncertainty below.

$V_{\text{stat}}$  contains the statistical uncertainty, which is less than 24% in each energy bin and 15% on average.  $V_{\text{norm}}$  contains a 1.6% uncertainty in the relative normalization of the CC sample between the ND and FD, and a corresponding 2.2% uncertainty for the NC sample. This accounts for uncertainties in reconstruction efficiencies. It was determined by a study in which a team of scanners looked at events in both detectors from both simulation and data to assess the level of reconstruction failures. No evidence for a mismodeling of the reconstruction failures was observed, and the values quoted for the uncertainties are the statistical precision to which the modeling could be tested.

$V_{\text{acc}}$  accounts for uncertainties on the acceptance and selection efficiency of the ND. These uncertainties were evaluated by varying event-selection requirements in the data and MC simulation to probe known weaknesses in the simulation. As these requirements were varied, the total variations in the ND data to MC ratios were taken as systematic uncertainties on the FD-to-ND ratios. The total

uncertainty included in  $V_{\text{acc}}$ , which is energy dependent and includes correlations between different bins, varies from 2% to 6% for the CC sample and is below 0.6% at all energies for the NC sample.

$V_{\text{NC}}$  accounts for an uncertainty on the procedure used to remove poorly reconstructed events from the NC sample. The variables used to identify such poorly reconstructed events are not perfectly modeled by the MC simulation. A procedure, described in Ref. [34], assesses an uncertainty arising from this mismodeling. The total uncertainty, which includes correlations between energy bins, falls from 5% below 1 GeV to less than 1.5% above 5 GeV.

$V_{\text{other}}$  includes terms to account for all sources of uncertainty in neutrino interaction cross sections and the flux of neutrinos produced in the NuMI beam. The total uncertainty on the FD-to-ND ratios arising from these sources is no more than 4% in any parts of the energy spectra.

We fit the 3 + 1 model to the data by dividing the  $(\sin^2\theta_{24}, \Delta m_{41}^2)$  plane into fine bins and minimizing Eq. (6) in each bin with respect to  $\Delta m_{32}^2$ ,  $\theta_{23}$ , and  $\theta_{34}$ . At each point in the plane we interpret the significance of the  $\Delta\chi^2$  with respect to the global minimum according to the unified procedure of Feldman and Cousins [35]. In this procedure, MC pseudoexperiments are generated, with bin-to-bin statistical and systematic fluctuations incorporated by sampling from a multidimensional Gaussian with covariance matrix  $V$  [defined in Eq. (7)]. The result is shown in Fig. 4, with the area to the right of the curves excluded at

FIG. 3. The effects of systematic uncertainties on the 90% CL sensitivity in the  $(\sin^2\theta_{24}, \Delta m_{41}^2)$  plane, shown by successive inclusion of the listed uncertainties.

FIG. 4. The MINOS 90% and 95% confidence limits in the  $(\sin^2\theta_{24}, \Delta m_{41}^2)$  plane compared with results from previous experiments [36–39]. The areas to the right of the MINOS lines are excluded at their respective confidence levels.

their respective confidence limits. The data are consistent with three-flavor oscillations at 54.7% CL; no evidence for sterile neutrinos is observed. The world's best limit on  $\sin^2 \theta_{24}$  is established for  $\Delta m_{41}^2 < 1 \text{ eV}^2$ , a largely unmeasured region of parameter space.

The limit obtained from the data is stronger than expected from the sensitivity, as can be seen from a comparison of Figs. 3 and 4. A study shows that 8% of fake experiments obtain an exclusion stronger than that obtained from the data at  $\Delta m_{41}^2 = 1 \text{ eV}^2$ . At  $\Delta m_{41}^2 = 0.5 \text{ eV}^2$ , the CC sample provides 75% of the  $\Delta\chi^2$  that gives rise to the 90% CL exclusion contour, with the NC sample providing the remaining 25%.

For  $\Delta m_{41}^2 < 10^{-2} \text{ eV}^2$  it becomes possible for one of the three mass splittings  $\Delta m_{41}^2$ ,  $\Delta m_{42}^2$ , or  $\Delta m_{43}^2$  to match the scale of oscillations in the  $\Delta m_{32}^2$  sector. This results in solutions that are degenerate with the standard three-flavor prediction, creating an island of allowed parameter space that is visible in Fig. 4.

Upper limits on the angles  $\theta_{24}$  and  $\theta_{34}$ , which correspond to limits on elements of the PMNS matrix, may be defined at fixed values of  $\Delta m_{41}^2$ . For  $\Delta m_{41}^2 = 0.5 \text{ eV}^2$ , the data constrain  $\sin^2 \theta_{24} < [0.016(90\% \text{ CL}), 0.022(95\% \text{ CL})]$ ; under the assumption that  $|U_{e4}|^2 = 0$ , these are also limits on  $|U_{\mu 4}|^2 = c_{14}^2 s_{24}^2$ . For  $\Delta m_{41}^2 = 0.5 \text{ eV}^2$ , the data also constrain  $\sin^2 \theta_{34} < [0.20(90\% \text{ CL}), 0.28(95\% \text{ CL})]$ ; under the assumption  $c_{14}^2 = c_{24}^2 = 1$ , these are also limits on  $|U_{\tau 4}|^2 = c_{14}^2 c_{24}^2 s_{34}^2$ .

In conclusion, we have used samples of CC  $\nu_\mu$  and NC interactions from the NuMI neutrino beam to place a constraint on the existence of sterile neutrinos. We use a  $3 + 1$  model to quantify this constraint, and are sensitive to a range of  $\Delta m_{41}^2$  covering almost 5 orders in magnitude. Over much of this region, we place the first constraints on the mixing angle  $\theta_{24}$ . In an accompanying Letter [40], we present a combination of this constraint with those on  $\theta_{14}$  from the Daya Bay [16] and Bugey [17] reactor experiments to set a limit that is directly comparable with the possible hints of sterile neutrinos seen by the LSND and MiniBooNE experiments.

This work was supported by the U.S. DOE, the U.K. STFC, the U.S. NSF, the State and University of Minnesota, and Brazil's FAPESP, CNPq and CAPES. We are grateful to the Minnesota Department of Natural Resources and the personnel of the Soudan Laboratory and Fermilab. We thank the Texas Advanced Computing Center at The University of Texas at Austin for the provision of computing resources. We thank A. Smirnov and C. Giunti for useful discussions.

*Note added.*—A paper by the IceCube Collaboration that sets limits using sterile-driven disappearance of muon neutrinos has recently appeared [41]. The results place

strong constraints on  $\sin^2 2\theta_{24}$  for  $\Delta m_{41}^2 \in (0.1, 10) \text{ eV}^2$ . Furthermore, a paper that reanalyses the same IceCube data in a model including nonstandard neutrino interactions has also recently appeared [42].
