Abstract

This article focuses on model-based clustering of subjects based on the shared relationships of subject-specific networks and covariates in scenarios when there are differences in the relationship between networks and covariates for different groups of subjects. It is also of interest to identify the network nodes significantly associated with each covariate in each cluster of subjects. To address these methodological questions, we propose a novel nonparametric Bayesian mixture modeling framework with an undirected network response and scalar predictors. The symmetric matrix coefficients corresponding to the scalar predictors of interest in each mixture component involve low-rankness and group sparsity within the low-rank structure. While the low-rank structure in the network coefficients adds parsimony and computational efficiency, the group sparsity within the low-rank structure enables drawing inference on network nodes and cells significantly associated with each scalar predictor. Being a principled Bayesian mixture modeling framework, our approach allows model-based identification
of the number of clusters, offers clustering uncertainty in terms of the co-clustering matrix and presents precise characterization of uncertainty in identifying network nodes significantly related to a predictor in each cluster. Empirical results in various simulation scenarios illustrate substantial inferential gains of the proposed framework in comparison with competitors. Analysis of a real brain connectome dataset using the proposed method provides interesting insights into the brain regions of interest (ROIs) significantly related to creative achievement in each cluster of subjects. Supplementary material shows the convergence rate for the posterior predictive density of the proposed model, additional simulation examples with model mis-specification and also presents traceplots for various model parameters to demonstrate convergence of the Markov Chain Monte Carlo (MCMC) algorithm.

*Keywords:* Bayesian mixture modeling, Network clustering, Network node selection, Spike and slab prior, Brain connectome data.

1 Introduction

In recent times, network data is regularly encountered in disciplines as diverse as neuroscience, genetics, finance and economics. This article is motivated by scenarios where an undirected network and several scalar variables are available for each subject in a multi-subject setting, and there are differences in the relationship between the network and covariates for different groups of subjects. In this context, we develop a novel non-parametric Bayesian regression framework with the network serving as the response, and scalar predictors. In particular, we focus on brain connectome data obtained using diffusion weighted magnetic resonance imaging (dMRI). Here, the human brain is segmented into structural regions of interest (ROIs), viewed as nodes of the brain network, and the number of fiber bundles connecting any pair of regions (an edge connecting a pair of nodes) is estimated. Thus the brain may be viewed as an undirected network expressed in the form of a symmetric matrix. Along with the brain networks, we have information on a brain related phenotype (creative achievement), as well as behavioral variables, for each subject, which serve as our scalar predictors.

Our modeling endeavor primarily aims at achieving the following inferential objectives
simultaneously. First, we intend to cluster subjects into groups, with members in each group sharing the same relationship between the undirected network response and scalar covariates. The clustering endeavor aims at model-based determination of the number and composition of clusters. Additionally, it offers clustering uncertainty in terms of the model-based estimation of the probability of a pair of observations being part of the same cluster. Second, inferential interest lies in identifying nodes and edges in the network significantly impacted by each predictor of interest in each cluster. To this end, an important inferential objective is to accurately characterize uncertainty in our inference on network nodes. For the brain connectome data, the latter objective amounts to drawing inference on brain regions of interest (ROIs) and their interconnections significantly associated with creative achievement in each cluster. We also offer uncertainty in terms of estimated probability of a node being identified as influential. Moreover, we would like to achieve these inferential goals with parsimony in the fitted model and computational efficiency in the model fitting process.

An overwhelming literature in network analysis aims at understanding the topological structure of a single network, rather than focusing on multiple network observations collected for different individuals. Some notable examples of single-network models include exponential random graph models (Frank and Strauss, 1986), social space models (Hoff, 2005) including random dot product graph (RDPG) models (Young and Scheinerman, 2007) and stochastic block models (Nowicki and Snijders, 2001). In the context of developing a regression/classification model with a network response, a possibility is to extract a few summary measures from the network to reshape the network object into a multivariate response (e.g., see Bullmore and Sporns, 2009 and references therein). Clearly, the success of this approach is highly dependent on the choice of summary measures. Furthermore, this approach cannot identify the impact of specific nodes on the predictor, which is of clear interest in our setting. In a newer work, Wang et al., 2017 exploit the relational nature of the network response, though their approach does not offer any clustering mechanism for the subjects and is not designed to detect network nodes significantly related to a scalar predictor. Another approach in the tensor regression literature, which assumes a general version of the tensor and does not consider the symmetry constraint (inherent in an undirected network), applies regression with a matrix/tensor response (Gahrooei et al., 2021; Guhaniyogi and Spencer,
2021). Some recent articles on supervised stochastic block models (Kim and Levina, 2019; Pavlović et al., 2020) focus on clustering the nodes of the network into groups, which is methodologically a different problem than ours, where the focus is on clustering subjects into groups.

While our framework treats the network as a response, a few recent approaches (Guha and Rodriguez, 2021; Relión et al., 2019) treat the network as a predictor to predict a scalar response. This difference in the modeling approach leads to a different focus and interpretation. Network predictor regression focuses on understanding variations in a biological outcome as the network image varies, while network response regression aims to study changes in the network as predictors such as the creativity levels, age and sex vary. In a sense, their difference is comparable to that of multi-response regression and multi-predictor regression in the classical vector-valued regression context. Importantly, our network-response regression framework bypasses the need to invert any high dimensional matrix to draw Bayesian inference, thereby adding substantial computational gains over Guha and Rodriguez, 2021, especially in the analysis of networks with a moderately large to a large number of nodes, when computation in Guha and Rodriguez, 2021 may become quite expensive. Note that a recent approach (Guha and Guhaniyogi, 2021) discusses symmetric tensor-on-vector regression models; however, both Guha and Guhaniyogi, 2021 and Guha and Rodriguez, 2021 tacitly assume that the same set of network nodes influence the regression function in a similar manner for every subject.

The neuroscience literature provides substantial evidence of differences in the relationship between brain connectivity networks and phenotypic traits for different groups of individuals (Saad et al., 2012; Meskaldji et al., 2013, 2015). However, flexible statistical methods for identifying such subgroups and ascertaining subgroup differences have somewhat lagged behind the increasingly routine collection of such data. One possibility is to flatten the network to a high dimensional multivariate vector and employ a mixture of multivariate regression models. This idea can make use of the literature on mixtures of supervised parametric and semi-parametric linear and generalized linear models with continuous, binary and categorical responses and predictors (Müller et al., 1996; Shahbaba and Neal, 2009; Duan et al., 2007; Rodríguez et al., 2009; Amewou-Atisso et al., 2003; Hannah et al., 2011). These ap-
proaches are less suitable for our problem of interest since they ignore the network topology in the model building process, and do not allow drawing inference on network nodes. In this context, one may invoke the literature on clustering of matrices or tensors into multiple groups (Huang et al., 2009; Lee et al., 2010; Chi and Lange, 2015; Chi et al., 2017; Li et al., 2014; Cao et al., 2013; Wu et al., 2016), but this literature is more pertinent to unsupervised clustering of networks, as opposed to our interest in supervised clustering of networks.

In this article, we propose a novel nonparametric Bayesian modeling approach to achieve the aforementioned inferential objectives simultaneously. A Dirichlet process (DP) mixture of network response regression models is developed and used to analyze the data, which leads to clustering of subjects into groups signifying differential relationships between the network response and scalar predictors. Further, the network valued coefficients corresponding to the predictors of interest in each mixture component are assumed to have a low-rank for parsimony and computational efficiency. We also impose a node-specific sparsity structure using a Bayesian spike-and-slab variable selection prior for identifying network nodes significantly associated with the predictors. Being a Bayesian mixture modeling framework, our method achieves model-based determination of the number of clusters and delivers model-based estimation of clustering uncertainty. Specifically, clustering uncertainty is quantified by estimating the posterior probability of any pair of observations being part of the same cluster. Additionally, the proposed method identifies network nodes significantly related to a predictor in each cluster, and characterizes uncertainty associated with identifying important network nodes in each cluster. The uncertainty is quantified by model-based estimation of posterior probability of a node being influentially related to a predictor. Unlike a frequentist approach, both the uncertainty in clustering as well as the uncertainty in the inference on nodes can be seamlessly estimated from the post burn-in Markov Chain Monte Carlo (MCMC) iterates of the proposed Bayesian approach. Such uncertainty characterizations are crucial in neuroscientific applications with a limited sample size, high dimensional parameters and low signal-to-noise ratio. Our framework does not involve any expensive matrix manipulation, allowing efficient computation with a large number of network nodes.

Our approach is fundamentally different from regression with a covariance matrix outcome and scalar predictors. These approaches tacitly use positive-definite property of the
outcome matrix (Hoff and Niu, 2012; Zou et al., 2017). A similar modeling framework is developed by Zhao et al. (2021), wherein important principal components of covariance matrix outcomes related to scalar covariates are identified. In contrast, we do not impose any restrictions on our network matrix response matrix (e.g., positive definiteness) except symmetry, which is directly motivated by the scientific problem at hand. Additionally, an important modeling objective lies in identifying network nodes (with uncertainties) significantly related to scalar predictors. The aforementioned approaches are not designed to deliver such inference.

The rest of this article progresses as follows. Sections 2 and 3 describe model development and posterior computation, respectively. Empirical investigation of the model with simulation studies and the brain connectome data analysis are presented in Sections 4 and 5, respectively. Finally, Section 6 concludes the paper with an eye towards future work. Theoretical investigations of the model, showing convergence rate of the posterior predictive distribution, are described in the supplementary material. Supplementary material also shows convergence of MCMC chains for model estimation by displaying traceplots of model parameters.

2 Supervised Clustering of Undirected Networks: Model and Prior Formulation

2.1 Notations and Framework

For \( i = 1, \ldots, n \), let \( Y_i \in \mathcal{Y} \in \mathbb{R}^{p \times p} \) denote the weighted undirected network response with \( p \) nodes, \( x_i = (x_{i1}, \ldots, x_{im})' \) be \( m \) predictors of interest and \( z_i = (z_{i1}, \ldots, z_{il})' \) be \( l \) auxiliary predictors corresponding to the \( i \)th individual. Mathematically, this amounts to \( Y_i \) being a \( p \times p \) matrix, with the \((j_1, j_2)\)-th entry of \( Y_i \) denoted by \( y_{i,(j_1,j_2)} \in \mathbb{R} \). In this article, we focus on networks that contain no self relationship, i.e., \( y_{i,(j_1,j_2)} \equiv 0 \) when \( j_1 = j_2 \), and are undirected \((y_{i,(j_1,j_2)} = y_{i,(j_2,j_1)})\).

We assume that the relationship between the predictor vector of interest \( x_i \) and the response varies in every cell \((j_1, j_2)\). In contrast, an auxiliary predictor explains the response in every cell identically. Let \( \mathcal{J} = \{ j = (j_1, j_2) : 1 \leq j_1 < j_2 \leq p \} \) be a set of indices. Since \( Y_i \)
is symmetric with 0 diagonal entries, it suffices to build a probabilistic generative mechanism for \( y_{i,j} (j \in \mathcal{J}) \). This is a common practice in the modeling of undirected relational data (Hoff et al., 2002; Hoff, 2005). Moreover, working with \((y_{i,j} : j \in \mathcal{J})\) is fundamentally different from the ordinary vectorization of \( Y_i \) for model fitting, since every element \( y_{i,j} \) of \( Y_i \) keeps a tab on the cell index \( j = (j_1, j_2) \) of the entry (i.e., position of the entry in the matrix), which will be crucial in the modeling development described below.

### 2.2 Model Development and Prior Distributions

To develop a sufficiently flexible relationship between \( Y_i \) and predictors \( x_i \) and \( z_i \), we propose to model the conditional distribution of \( Y_i | x_i, z_i, \sigma^2 \), denoted by \( f(Y_i | x_i, z_i, \sigma^2) \) as a mixture model given by,

\[
    f(Y_i | x_i, z_i, \sigma^2) = \int g(Y_i | x_i, z_i, B_1, \ldots, B_m, \gamma_0, \ldots, \gamma_l, \sigma^2) dG(B_1, \ldots, B_m, \gamma_0, \gamma_1, \ldots, \gamma_l),
\]

where \( g(Y_i | x_i, z_i, B_1, \ldots, B_m, \gamma_0, \ldots, \gamma_l, \sigma^2) \) is suitably chosen from the class of exponential family distributions depending on whether each \( y_{i,j} \) is continuous, binary or categorical. In this article, we focus on the case where each network edge \( y_{i,j} \) is continuous, and choose \( g(\cdot) \) such that each \( y_{i,j} (j \in \mathcal{J}) \) is normally distributed with its probabilistic generative mechanism given by

\[
    y_{i,j} = \gamma_0 + \sum_{s=1}^l \gamma_s z_{is} + \sum_{s=1}^m B_{s,j} x_{is} + e_{i,j}, \quad e_{i,j} \sim N(0, \sigma^2). \tag{2}
\]

Supplementary material presents performance of (2) when it is mis-specified, e.g., the continuous edge effects \( y_{i,j} \)'s are generated from a heavy-tailed t-distribution in the truth. The coefficients \( B_{1,j}, \ldots, B_{m,j} \) are the \( j \)-th cells of the symmetric matrix coefficients \( B_1, \ldots, B_m \) of order \( p \times p \) with zero diagonal entries, respectively. Here \( \gamma_0 \) is the intercept and \( \gamma_1, \ldots, \gamma_l \in \mathbb{R} \) are coefficients corresponding to the auxiliary predictors. The model formulation implies a similar effect of any of the auxiliary variables \( z_{i1}, \ldots, z_{il} \) on all cells of the response tensor in each mixture component. In contrast, \( B_{s,j} \) determines the effect of \( x_{is} \) on the \( j = (j_1, j_2) \)-th cell of the response in any mixture component. Equations (1) and (2) together can be seen
as a mixture of undirected network response regression models with the mixing distribution given by $G(\cdot)$. Note that (1) is markedly different from building an ordinary mixture of linear regression models with vectorized network response $Y_i$ and scalar predictors. Vectorization of the $Y_i$ network matrix would have led to a long vector, which would be a collection of network edges. But such a construction would lose the crucial information regarding the pair of nodes that each edge is connected to. Since our interest lies in drawing inference on network nodes significantly associated with a scalar predictor, such a vectorization strategy is inadequate. In contrast, (2) develops a regression model for each edge on scalar predictors while keeping a tab on the nodes, $j_1$ and $j_2$, that the edge $y_{i,j}$ is connected to. The edge coefficient $B_{s,j}$ in (2) is suitably modeled, exploiting this information, to draw inference on network nodes significantly related to the predictors. It is important to note that the prior literature on network data modeling and tensor regression models also use a similar strategy (Hoff, 2005; Guhaniyogi et al., 2017; Guha and Guhaniyogi, 2021). We further elaborate on this point as this section progresses.

The random probability measure $G(\cdot)$ is taken to be a discrete distribution of the form $G = \sum_{h=1}^{H} \omega_h \delta_{\Delta^*_h}$, with atoms $\Delta^*_h = (B^*_{1,h}, ..., B^*_{m,h}, \gamma^*_0,h, \gamma^*_1,h, ..., \gamma^*_l,h) \sim G_0$. Here $G_0$ is the base measure and $\delta_{\Delta^*_h}$ corresponds to the Dirac-delta function at $\Delta^*_h$. Such a specification contains a broad class of species sampling priors, including the Dirichlet process (DP) prior and the Pitman-Yor process prior through the popular stick breaking construction (Sethuraman, 1994). In this work, we adopt the stick breaking construction to jointly model cluster inclusion probabilities. More precisely, for $h = 1, ..., H - 1$, and $\alpha > 0$,

$$\omega_1 = v^*_1, \omega_2 = v^*_2(1-v^*_1), ..., \omega_{H-1} = v^*_{H-1} \prod_{h=1}^{H-2} (1-v^*_h), \omega_H = \prod_{h=1}^{H-1} (1-v^*_h), v^*_h \sim Beta(1, \alpha),$$

(3)

where $H$ is an upper bound on the number of clusters. As $H \to \infty$, this choice leads to the classical Dirichlet process prior (Ishwaran and James, 2002). The parameter $\alpha$ is crucial in determining the number of clusters and it is assigned a $Gamma(a_\alpha, b_\alpha)$ prior distribution.

From (1) and the discrete prior on $G$ imposed by the stick breaking construction, the
conditional distribution of $Y_i$ can be written as
\[
f(Y_i|x_i, z_i, \sigma^2) = \sum_{h=1}^{H} \omega_h g(Y_i|x_i, z_i, B_{1,h}^*, \ldots, B_{m,h}^*, \gamma_{0,h}^*, \ldots, \gamma_{l,h}^*, \sigma^2).
\] (4)

The mixture components signify different relationships between the network response and scalar predictors in $H$ different clusters. We introduce a cluster index $c_i \in \{1, \ldots, H\}$ corresponding to the individual $i$, $Y_i|x_i, z_i, c_i, \sigma^2 \sim g(Y_i|x_i, z_i, B_{s,h}^*, c_i, \ldots, B_{m,c_i}^*, \gamma_{0,c_i}^*, \ldots, \gamma_{l,c_i}^*, \sigma^2)$, with $P(c_i = h) = \omega_h$, for $h = 1, \ldots, H$. This conditional independence structure, given the cluster indices of the individuals, facilitates computation, while still allowing a flexible dependence structure among the different components marginally. Additionally, inference on cluster indices determine the number of clusters and constitution of each cluster.

In order to identify network nodes in different clusters significantly associated with predictors of interest, we first introduce a low-rank structure of the coefficient $B_{s,h}^* = (B_{s,h,j})_{j_1,j_2=1}^p$ corresponding to the $s$th predictor of interest in the $h$th cluster as
\[
B_{s,h,j}^* = \sum_{r=1}^{R} \lambda_{s,h,r} u_{s,h,j_1}^{(r)} u_{s,h,j_2}^{(r)}, \quad h = 1, \ldots, H; \quad s = 1, \ldots, m, \quad 1 \leq j_1 < j_2 \leq p.
\] (5)

Here $u_{s,h,k} = (u_{s,h,k}^{(1)}, \ldots, u_{s,h,k}^{(R)})' \in \mathbb{R}^R$, for $k = 1, \ldots, p$, is a collection of $R$-dimensional $h$-th mixture specific latent variables, one for each node and each predictor of interest, such that $u_{s,h,k}$ corresponds to node $k$ and predictor $x_s$ in the $h$-th mixture component, and $\lambda_{s,h,r} \in \{-1, 0, 1\}$ determines if the $r$th summand in (5) is relevant in model fitting in the $h$th mixture component. Setting $U_{s,h}$ as a $p \times R$ matrix with the $k$-th row as $u_{s,h,k}$ ($k = 1, \ldots, p$), and $\Lambda_{s,h}$ a $R \times R$ diagonal matrix with the $r$-th diagonal entry as $\lambda_{s,h,r}$, (5) represents a low-rank decomposition of the symmetric matrix coefficient $B_{s,h}^* = U_{s,h} \Lambda_{s,h} U_{s,h}'$. Since the choice of $R$ is arbitrary, allowing $\lambda_{s,h,r}$ to be 0 protects the model from over-fitting. The low-rank formulation of $B_{s,h}^*$ is motivated by several considerations simultaneously. In practice, the matrix of coefficients $B_{s,h}^*$ is expected to exhibit transitivity effects, i.e., we expect that if the interactions between nodes $j_1$ and $j_2$ and between nodes $j_2$ and $j_3$ are both influentially related to the $s$th predictor of interest, the interaction between nodes $j_1$ and $j_3$ is likely to be influential as well (e.g., see Li et al., 2013). Such an effect is a natural outcome of the
low-rank formulation of $B^*_{s,h}$. Second, the low-rank formulation allows inference on network nodes through the node-specific latent vectors $u_{s,h,1}, \ldots, u_{s,h,p}$, which can be interpreted as the positions of the nodes in a latent space, with the strength of the association $B^*_{s,h}$ being controlled by the inner product or the angular distance between the vectors. The assumed low-rank structure on $B^*_{1,h}, \ldots, B^*_{m,h}$ additionally offers parsimony by reducing the number of estimable parameters from $mHp(p-1)/2$ to $mHRp$, typically with $R \ll p$.

Depending on the structure of $\Lambda_{s,h}$, the node specific latent variables $u_{s,h,k}$’s may become unidentifiable. For example, when $\Lambda_{s,h} = I_R$, $B^*_{s,h} = U_{s,h} \Lambda_{s,h} U_{s,h}' = U_{s,h} O \Lambda_{s,h} (U_{s,h} O)'$, for any orthogonal matrix $O$. While this implies that posterior inference on $u_{s,h,k}$’s (without any constraint imposed on $u_{s,h,k}$’s) may not always be meaningful, our focus is on the event $\{u_{s,h,k} = 0\}$ for each $k$, which is indeed identifiable (since 0-valued latent vectors are invariant to orthogonal transformation) and is critical to drawing inference on the nodes related to the $s$-th predictor of interest, as we describe next. To infer on the network nodes significantly related to the predictors of interest in each cluster, we assign a spike-and-slab prior on node specific latent variables as below,

$$
\begin{align*}
    u_{s,h,k} &\sim \begin{cases} 
        N(0, M_{s,h}), & \text{if } \xi_{s,h,k} = 1 \\
        \delta_0, & \text{if } \xi_{s,h,k} = 0
    \end{cases}, \\
    \xi_{s,h,k} &\sim \text{Ber}(\zeta_{s,h}), \\
    M_{s,h} &\sim \text{IW}(\nu, I), \\
    \zeta_{s,h} &\sim \text{Beta}(a, b).
\end{align*}
$$

(6)

where $M_{s,h}$ is a covariance matrix of order $R \times R$. The parameter $\zeta_{s,h}$ corresponds to the probability of the nonzero mixture component in (6). Importantly, $\xi_{s,h,k} = 0$ implies that the $k$th network node in the response is not related to the $s$th predictor in the $h$th cluster of subjects. In order to learn how many summands in (5) are informative, we draw inference on $R_{eff,s} = \sum_{r=1}^R |\lambda_{s,h,r}|$ by assigning a hierarchical prior

$$
\lambda_{s,h,r} \sim \begin{cases} 
    0, & \text{w.p. } \pi_{s,h,r,1} \\
    1, & \text{w.p. } \pi_{s,h,r,2} \\
    -1, & \text{w.p. } \pi_{s,h,r,3}
\end{cases}, \\
(\pi_{s,h,r,1}, \pi_{s,h,r,2}, \pi_{s,h,r,3}) \sim \text{Dirichlet}(r^{\eta}, 1, 1), \ \eta > 1.
$$

The choice of hyper-parameters of the Dirichlet distribution is crucial. In particular, note
that (i) $E[|\lambda_{s,h,r}|] = 2/(2 + r^\eta) \to 0$ as $r \to \infty$ and that (ii) \[ \sum_{r=1}^{R} \text{Var}(|\lambda_{s,h,r}|) = \frac{2(\eta+1)}{(\eta+2)^2(\eta+3)} + \frac{2r(\eta+1)}{(\eta+3)^2(\eta+4)} \to \infty \text{ as } R \to \infty. \]

Property (i) provides (weak) identifiability of the different latent dimensions, while property (ii) ensures that $\lim_{R \to \infty} \text{Var}(R_{eff,s}) < \infty$.

The parameters $\gamma_{0,h}^*, \gamma_{1,h}^*, \ldots, \gamma_{L,h}^*$ are assigned standard normal distributions and the error variance $\sigma^2$ is assigned IG($a_\sigma, b_\sigma$) a-priori. With the construction specified above, the form of the base measure $G_0$ can be expressed as $G_0(\Delta^*_{k} | \sigma^2) = \prod_{s=0}^{L} G_{0,1}(\gamma_{s,h}^* | \sigma^2) \prod_{s=1}^{m} G_{0,2}(B_{s,h}^* | \sigma^2)$, where $G_{0,1}(\gamma_{s,h}^* | \sigma^2) = N(0, 1)$, and $G_{0,2}(B_{s,h}^* | \sigma^2)$ is expressed as follows:

$$G_{0,2}(B_{s,h}^* | \sigma^2) = \int \prod_{k=1}^{p} \pi(u_{s,h,k} | \xi_{s,h,k}, M_{s,h}, \zeta_{s,h}) \int_{r=1}^{R} \int_{r=1}^{R} \int_{r=1}^{R} \prod_{k=1}^{p} \pi(\lambda_{s,h,r}) \prod_{k=1}^{p} \pi(\xi_{s,h,k}) d\xi_{s,h,k}.$$

The model and prior specifications allow clustering of individuals into a number of groups less than or equal to $H$. In each group, the network response and scalar predictors share separate regression structures, and thus subjects belonging to different clusters may have different sets of network nodes significantly related to the predictors of interest, as desired.

3 Posterior Computation

While fitting our proposed mixture model, we adopt a moderately large choice of $H$. Note that, according to Rousseau and Mengersen (2011), a similar choice of prior as ours is effective in the deletion of redundant mixture components not needed to characterize the data. If a specific choice of $H$ leads to all of the clusters being occupied, then the analysis should be repeated for a larger $H$ until there is at least one unoccupied cluster. Since all parameters except $\alpha$ have full conditional posterior distributions belonging to standard families of distributions, Gibbs sampling with Metropolis is implemented to empirically estimate posterior distributions. Details of the Markov chain Monte Carlo algorithm are presented in the Appendix. We have implemented our code in R (without using any C++, Fortran or Python interface) on a cluster computing environment with three interactive analysis servers, 56 cores each with the Dell PE R820: 4x Intel Xeon Sandy Bridge E5-4640 processor, 16GB RAM and 1TB SATA hard drive.

**Indicators to assess clustering performance.** To assess inference from the proposed mixture model, we investigate (i) a point estimate of clustering denoted by $\hat{c}$, (ii) a heatmap
of the posterior probabilities of pairs of samples belonging to the same cluster, i.e., \( P(c_i = c_j | Y_1, \ldots, Y_n) \) (which provides a measure of the uncertainty associated with the clustering), and (iii) a histogram of the posterior distribution of the number of identified clusters. The point estimate \( \hat{c} \) is obtained by minimizing (using iterative component-wise optimization) the expected loss function discussed in Lau and Green, 2007,

\[
F(\hat{c}) = \sum_{i=1}^{n} \sum_{j=i+1}^{n} 1(\hat{c}_i = \hat{c}_j) \left[ \frac{o_2}{o_1 + o_2} - P(c_i = c_j | Y_1, \ldots, Y_n) \right],
\]

where the ratio \( o_1/o_2 \) controls the relative loss due to incorrect clustering or separation of a pair of samples. Without any prior knowledge, we assume the loss due to incorrectly clustering and separating any pair of samples is the same, by setting \( o_1/o_2 = 1 \).

4 Simulation Studies

This section studies the relative performance of our proposed network response mixture model (NRMM) vis-a-vis its competitors. To study all competitors under various data generation schemes, we simulate the network response \( Y_i \), depending on the predictors \( x_i \) and \( z_i \), from the finite mixture model given by

\[
Y_i | x_i, z_i \sim \sum_{h=1}^{H_0} \omega_{h,0} g(Y_i | x_i, z_i, B_{1,h,0}^*, \ldots, B_{m,h,0}^*, \rho_{0,h,0}^*, \gamma_{0,h,0}^*, \ldots, \gamma_{l,h,0}^*, \sigma_{0,h,0}^2), \quad i = 1, \ldots, n + n_0.
\]

The first \( n \) observations \( \{(Y_i, x_i, z_i) : i = 1, \ldots, n\} \) are used for model fitting and the rest \( n_0 \) observations are used for out-of-sample inference. Here \( g(\cdot) \) is as described in equation (2), and \( B_{s,h,0}^*, s = 1, \ldots, m, h = 1, \ldots, H_0 \) are mixture specific coefficients for \( x_{is} \). Section 3 of the supplementary material shows performance of the proposed approach and its competitors under model mis-specification, i.e., when each \( y_{i,j} \) is generated from a heavy-tailed t-distribution. The parameter \( \gamma_{0,h,0}^* \) is the \( h \)th mixture specific intercept and \( \gamma_{1,h,0}^*, \ldots, \gamma_{l,h,0}^* \) are the \( h \)th mixture specific coefficients corresponding to \( z_{i1}, \ldots, z_{il} \), respectively. We set \( m = 1 \) and \( l = 2 \) for the simulations, which mimics the real data application scenario. Since \( m = 1 \), the subscript \( s \) will be omitted from variables related to the predictor of interest hereon. The predictors \( x_i, z_{i1} \) and \( z_{i2} \) are simulated i.i.d. from \( N(0,1) \).
To simulate the coefficients $B_{h,0}^*$, we draw $p$ latent variables $u_{h,k,0}$, each of dimension $R_g$, from a mixture distribution given by

$$u_{h,k,0} \sim \pi_0 N_R_g(u_{h,m,g}, u_{h,v,g}^2 I_{R_g}) + (1 - \pi_0) \delta_0; \quad k \in \{1,...,p\}, \quad (9)$$

where $N_R_g(u_{h,m,g}, u_{h,v,g}^2 I_{R_g})$ represents an $R_g$-variate normal distribution with mean vector $u_{h,m,g}$ and covariance matrix $u_{h,v,g}^2 I_{R_g}$. Also, $(1 - \pi_0)$ is the probability of any $u_{h,k,0}$ being zero in the truth, $h = 1,...,H_0$, and is referred to as the network node sparsity. We consider 10 simulation cases as following:

**Cases 1-8:** In Cases 1-8, the $j = (j_1, j_2)$th element $(j_1 < j_2)$ of $B_{h,0}^*$ corresponding to the $h$-th mixture component is constructed using a low-rank approach $B_{h,0,j}^* = u_{h,j_1,0}^t u_{h,j_2,0}$, accounting for the interaction between the $j_1$th and $j_2$th network nodes, for all $h = 1,...,H_0$. The diagonal entries of $B_{h,0}^*$ are set to zero, and the lower triangular part of $B_{h,0}^*$ is a mirror image of the upper triangular part. The 8 different cases are obtained by varying the number of true mixture components ($H_0$), number of network nodes ($p$), sample size ($n$), true dimension of latent variables ($R_g$), fitted dimension of latent variables ($R$) and network node sparsity $(1 - \pi_0)$, as summarized in Table 1.

**Case 9:** In Case 9, we consider $H_0 = 2$, $\omega_{1,0} = 0.4, \omega_{3,0} = 0.6$, and $B_{1,0}^*$ and $B_{2,0}^*$ are simulated using two different strategies as following:

**Simulating $B_{1,0}^*$:** The $j = (j_1, j_2)$th element $(j_1 < j_2)$ of $B_{1,0}^*$ is constructed using a low-rank approach $B_{1,0,j}^* = u_{1,j_1,0}^t u_{1,j_2,0}$, where the sparsity $(1 - \pi_0)$ in generating the latent variables is set at 0.6. The diagonals of $B_{1,0}^*$ are set to zero and the lower triangular part is a mirror image of the upper triangular part.

**Simulating $B_{2,0}^*$:** Randomly set $(1 - \pi_0) = 0.6$ proportion of upper triangular elements in $B_{2,0}^*$ to zero, while the rest are simulated from $N(0,1)$. The diagonals of $B_{2,0}^*$ are set to zero and the lower triangular part is a mirror image of the upper triangular part.

**Case 10:** Case 10 uses an identical construct as Case 9, except that $(1 - \pi_0)$ is set at 0.3.

The intercept $\gamma_{s,h,0}^*$, $h = 1,...,H_0$, $s = 1,2$ in each mixture component is drawn from $N(-2,2)$, while $\sigma_0^2$ is fixed at 0.5.

In all cases, each component of the mean vector $u_{h,m,g}$ is randomly generated to lie
Table 1: Table presents specifications of Cases 1-8 in the simulation study. The parameter $H_0$ refers to the true number of mixture components in the Bayesian network response mixture model (NRMM). Different cases present various combinations of the number of network nodes $p$, fitted sample size $n$, number of subjects $n_0$ for out-of-sample inference, network node sparsity $(1 - \pi_0)$, true ($R_g$) and fitted ($R$) dimensions of the node specific latent variables.

between $(-2, 2)$ and the standard deviation $u_{h,v,g}$ is set randomly at a number between 0.3 and 2.

Notably, **Cases 1-6** represent scenarios with heterogeneous settings where $H_0 > 1$, i.e., the true data generating model is a mixture of more than one network response regression model. In contrast, Cases 7 and 8 correspond to the homogeneous setting with $H_0 = 1$, i.e., the true model constitutes a single network response regression model. Also, it is important to note that **Cases 1-8** represent the true model being included in the class of fitted models. In contrast, **Cases 9 and 10** show departure of the true model from the fitted models. In particular, the last two cases include specifications where the network coefficient in a cluster is full rank, whereas the fitted model assumes a low-rank structure for network coefficients in all the clusters. This will allow assessing the performance of our approach under model mis-specification. Notably, for any $p$ (i.e., the number of network nodes), the model needs to estimate $mHRp$ parameters, so that even moderately large values of $p$ in Cases 1-10 lead to high dimensional regression settings. In all simulations, we set $p < n$, which is a sufficient condition for convergence of the fitted predictive density to the true predictive density (see Theorem 1.1 in the Supplementary Material).
4.1 Choice of Hyper-parameters

All simulation settings and the real data analysis are presented with the hyper-parameters chosen as $a = 1, b = 1, a_\sigma = 1, b_\sigma = 1$ and $\nu = 20$. The choice of $a_\sigma = b_\sigma = 1$ ensures that the prior on $\sigma^2$ is sufficiently flat with an infinite mean. The choice of $a = b = 1$ leads to a-priori uniform distribution on the number of network nodes related to each predictor in each cluster. Setting $\nu = 20$ implies that the prior distribution of $M_h$ is concentrated around a scaled identity matrix. Since the model is invariant to rotations of the latent positions $u_{h,k}$, the prior on $u_{h,k}$’s should ideally be invariant under rotation. Centering $M_h$ around a matrix that is proportional to the identity satisfies such a requirement. Finally, we choose $a_\alpha, b_\alpha$ following Escobar and West (1995) such that the mean number of clusters is approximately 2.5 a-priori. Since in most applications of the mixture model, the true number of clusters is small, our choice of $a_\alpha$ and $b_\alpha$ represent a reasonable prior belief. Moderately perturbing hyper-parameters yields practically identical inference, as described in Section 4.5.

4.2 Competitors and Metrics of Evaluation

NRMM is fitted in all simulations with $H = 15$ mixture components and it is allowed to identify the unknown and true number of mixtures from the data. As a competitor to our model, we employ the network response regression (NRR), which is essentially our proposed framework with only one mixture component, i.e., $H = 1$. Thus NRR assumes (a) the same set of network nodes is significantly related to the predictors of interest for every individual, and, (b) normality for the distribution of each cell in the network response. Comparison with NRR will highlight any relative advantages of NRMM when these assumptions do not hold true. However, we also include simulation cases 7 and 8 where data are simulated from the NRR model (i.e., there is only one mixture component), and hence data are likely to favor NRR over NRMM. Additionally, we compare our approach with a frequentist higher order low-rank regression (HOLRR) method (Rabusseau and Kadri, 2016) popularly used in machine learning. This approach also assumes a homogeneous setting and a low-rank decomposition for matrix coefficients without the ability of identifying influential network nodes with uncertainties.

The competitors are assessed based on their ability to estimate the true regression mean
function $E_0[y_i,j|x_i,z_i] = \sum_{h=1}^{H_0} \omega_{h,0} \left( \gamma^*_{0,h,0} + \sum_{s=1}^{l} \gamma^*_{s,h,0} z_{is} + \sum_{s=1}^{m} B^*_{s,h,0,j} x_{is} \right)$ for both in-sample and out-of-sample observations. In particular, the mean squared error (MSE) of estimating the true regression mean function over the in-sample fitted data and out-of-sample observations are given by,

$$\text{MSE} = \frac{2}{np(p-1)} \sum_{i=1}^{n} \left| \left| E_0[Y_i|x_i,z_i] - E[\hat{Y}_i|x_i,z_i] \right| \right|^2,$$

$$\text{MSE(out)} = \frac{2}{n_0p(p-1)} \sum_{i=n+1}^{n+n_0} \left| \left| E_0[Y_i|x_i,z_i] - E[\hat{Y}_i|x_i,z_i] \right| \right|^2,$$

(10)

where $E[\hat{Y}_i|x_i,z_i]$ denotes the posterior mean of the regression function for a competing method. While MSE offers an evaluation of the point estimation by competitors in-sample, MSE(out) evaluates the point estimation by competitors out-of-sample. The uncertainty in estimating the true regression mean function in-sample is measured using the coverage and length of 95% credible intervals obtained from NRMM and NRR. HOLRR being a frequentist method, coverage and length of 95% confidence intervals from HOLRR are not readily available. Thus, we invoke normal approximation wherein the 95% confidence interval for $E_0[y_i,j|x_i,z_i]$ is constructed by $(E[\hat{y}_{i,j}|x_i,z_i] - 1.96 \times se(E[\hat{y}_{i,j}|x_i,z_i]), E[\hat{y}_{i,j}|x_i,z_i] + 1.96 \times se(E[\hat{y}_{i,j}|x_i,z_i])$, where $se(E[\hat{y}_{i,j}|x_i,z_i])$ denotes the standard error of estimating the regression mean function in-sample.

In addition to reporting the posterior distribution of the number of clusters and the uncertainty associated with clustering through $P(c_i = c_j|Y_1, \ldots, Y_n)$, we also evaluate the ability of the models to identify clusters using the Adjusted Rand Index (ARI) (Hubert and Arabie, 1985) of the posterior cluster configurations with respect to the known cluster configuration. The ARI evaluates the agreement in cluster assignment between two cluster configurations. ARI is upper bounded by 1, with values close to 1 indicating more agreement between cluster configurations.

### 4.3 Simulation Results

All model parameters show excellent convergence with fairly uncorrelated post burn-in samples to draw posterior inference. To demonstrate this, we present the effective sample
size (ESS) corresponding to 10000 post burn-in samples from NRMM for all simulation examples (see Table 2). Section 4 of the supplementary material shows traceplots for a few parameters, and demonstrate excellent convergence. Table 2 and Figure 1 provide insights into the estimates of the cluster structure and associated uncertainty by displaying the discrepancy between the true and estimated number of clusters and heat maps of posterior probabilities of pairs of subjects belonging to the same cluster. To facilitate visualization in Figure 1, subjects are ordered according to their true cluster configurations in the heatmap. In all cases, the model successfully recovers the true cluster structure, with little uncertainty associated with the estimator. Importantly, the mixture model also successfully identifies only one cluster when the true data generation setting is homogeneous (cases 7-8). The most challenging cases among all are cases 9 and 10, which correspond to model mis-specification. Even with model mis-specification, there is a minor deterioration in the performance, with ARI dropping to around 0.93 in case 9 and 0.95 in case 10. It appears from Figure 1 that the clustering performance improves nominally with decreasing sparsity of $B_{h,0}^*$, the impact of sparsity being a little more prominent under model mis-specification (compare cases 9 and 10). The uncertainty in clustering for a few individuals also appears to be higher in case 8, where the true data generating model is homogeneous with $H_0 = 1$.

The posterior distributions of the number of identified clusters are also presented in the form of barplots in Figure 2. The posterior distribution of the number of clusters appears to concentrate around the true number of clusters $H_0$ in all cases except case 9, where the model mildly overestimates the number of clusters. Notably, case 9 corresponds to model mis-specification with a higher node sparsity parameter $(1 - \pi_0)$. As the node sparsity parameter $(1 - \pi_0)$ decreases, the posterior distribution of the number of clusters concentrates around $H_0$ even under model mis-specification (case 10). The results also reveal a somewhat bi-modal structure of the posterior distribution of the number of clusters under cases 3 (with $H_0 = 4$) and 8 (with $H_0 = 1$). Importantly, out of $H$ assigned clusters, most are not populated in each case, justifying the choice of $H = 15$ in each case.

Table 2 presents in-sample MSE and out-of-sample MSE(out) for estimating the regression mean function for all competitors. Further, coverage and average length of 95% credible intervals for NRMM and NRR, and 95% confidence intervals for HOLRR are provided to
(a) Case 1, $H_0 = 3$
(b) Case 2, $H_0 = 3$
(c) Case 3, $H_0 = 4$
(d) Case 4, $H_0 = 3$
(e) Case 5, $H_0 = 3$
(f) Case 6, $H_0 = 2$
(g) Case 7, $H_0 = 1$
(h) Case 8, $H_0 = 1$
(i) Case 9, $H_0 = 2$
(j) Case 10, $H_0 = 2$

Figure 1: Plots showing uncertainty in estimating clusters in simulation cases 1-10. Boldfaced horizontal and vertical lines indicate the true clustering.
Figure 2: Plots showing the posterior distribution of the number of clusters in the simulation cases 1-10.
Table 2: The first column presents Effective sample size (ESS) for NRMM corresponding to the 10000 post burn-in iterations to assess the convergence of the MCMC sampler for NRMM. The second column presents ARI values to assess the clustering accuracy of NRMM. The next two columns present True Positive Rates (TPR) and False Positive Rates (FPR) in identifying network nodes related to the predictor of interest in NRMM. MSE and MSE(out) for NRMM, NRR and HOLRR are presented for cases 1-10. The lowest MSE in each case is boldfaced. Coverage and length of 95% credible interval are provided for NRMM, NRR and HOLRR.

</table>
assess uncertainty quantification for regression mean functions in-sample. A few interesting observations emerge from Table 2. Comparing cases 1 and 2 (and also comparing cases 4 and 5), it turns out that NRMM yields marginally lower MSE with increased values of the sparsity parameter \((1 - \pi_0)\). Results from cases 9 and 10 present a similar trend, even under model mis-specification. Also, keeping \(n\) fixed and increasing \(p\) moderately does not have any significant impact on MSE. Increasing the number of true mixture components \(H_0\) has an adverse effect on the performance of NRMM, which becomes evident by comparing results from case 3 with cases 1 and 2. The out-of-sample inference on regression mean function follow very similar trends as suggested by the MSE(out) values. As expected, out-of-sample MSE values are always higher than in-sample MSE values. Additionally, in most cases, NRMM shows higher coverage levels, often close to nominal coverage, compared to NRR. The less than nominal coverage in cases 9 and 10 can be attributed to model mis-specification, whereas the under-coverage in case 3 could be due to the larger number of mixture components, which presents obstacles in model estimation. Note that under cases 7 and 8, only one mixture component (homogeneous setting) is used to simulate the data, and so the data favors NRR over NRMM. Consequently, NRR yields smaller MSE and close to nominal coverage in this case. Under all other cases with \(H_0 > 1\), NRR demonstrates inferior performance to NRMM with a higher MSE and considerable under-coverage of the mean function. HOLRR offers a higher MSE compared to NRMM under all simulation scenarios. The construction of 95% confidence intervals for HOLRR based on the asymptotic normal approximation result in much wider intervals with coverage close to 1.

Note that inference on each cluster is not readily available from the mixture model due to the clusters not being identifiable. Thus, to draw inference on which network nodes are influential in each cluster, we fix the cluster membership indicator \(c_i\) for the \(i\)th sample at \(\hat{c}_i\) (the estimated cluster indicator) and run the model once more without updating the cluster membership indicator \(c_i\) at any MCMC iteration. With the clusters remaining fixed in every iteration, it is possible to draw inference on the influential network nodes in each cluster. In particular, the \(k\)th node is deemed influential for the \(h\)th cluster, if the empirically estimated posterior probability of the event \(\{u_{h,k} \neq 0\}\) exceeds 0.5. As demonstrated in Figures 1 and 2, for cases 1-8, our proposed model correctly identifies each cluster in every simulation,
Table 3: Computation time (in seconds) per MCMC iteration of the NRMM model with $H = 15$ mixture components. The number of network nodes ($p$) and the sample size ($n$) are varied.

</table>

and hence inference on influential network nodes in each cluster as mentioned above can be directly compared to the truly influential nodes in each cluster for these simulation cases (i.e., under no model mis-specification). In this regard, Table 2 presents the True Positive Rates (TPR) = $\frac{TP}{TP+FP}$ and False Positive Rates (FPR) = $\frac{FP}{TN+FP}$ of identifying influential network nodes over all clusters, where TP, FP and TN denote the total number of true positives, false positives and true negatives, respectively. The results indicate high TPR and low FPR in all cases, except in case 3, which shows a comparatively lower TPR than the rest, but still a very low FPR. This observation may be attributed to a higher number of true clusters, where the model detects some influential nodes as uninfluential, resulting in decrease of TPR. Overall, the simulation studies indicate good performance of NRMM.

4.4 Computational Complexity and Time

In our framework, the Gibbs sampler for model estimation does not involve any expensive matrix inversion or multiplication, leading to fast computation. In fact, the Gibbs sampler can be suitably parallelized since the updates of $u_{s,h,k}$ can be performed over different processors in parallel. Computation times (in seconds) per MCMC iteration for the NRMM model (for varying number of network nodes, $p$, and sample size $n$) without parallelization are provided in Table 3. The entries in the table are recorded corresponding to $H = 15$ mixture components fitted to the data.

4.5 Sensitivity Analysis

To check sensitivity of inference to the choice of hyper-parameters, we consider a representative case (case 2) and re-analyze the same simulated data with different combinations of hyper-parameters. In particular, we consider three different hyper-parameter settings for case 2 and compare the inference with the results on case 2 presented earlier. The
Table 4: Sensitivity Analysis: ARI, MSE, MSE(out), coverage of 95% CI and length of 95% CI for NRMM in Case 2 with different hyper-parameter combinations are provided.

<table>
<thead>
<tr>

three combinations are given by, (i) $a = 1, b = 5, \nu = 20$; (ii) $a = 5, b = 1, \nu = 20$; (iii) $a = 1, b = 1, \nu = 50$. Note that (i) presents a low prior mean of 0.2 for each $\xi_{h,k}$ encouraging less number of activated nodes a-priori, whereas (ii) presents a higher prior mean of 5 for $\xi_{h,k}$ which encourages a higher number of activated nodes. Combination (iii) presents a variation of the hyperparameter $\nu$ in the Inverse-Wishart distribution of $M_h$. Table 4 shows the posterior mean of ARI in case 2 under the three different hyper-parameter settings. We additionally present MSE, MSE(out), coverage and length of 95% credible intervals for these hyper-parameter combinations and compare these results with the result presented for case 2 in Table 2. Of all the parameters, only variations in $a$ and $b$ seem to have an effect on the inference, but this effect is found to be very small. More specifically, when the prior mean of the number of activated nodes is small (combination (i)), both MSE and MSE(out) are found to be a little higher than what is presented in Table 2 under case 2. Similarly, the coverage is found to be a little lower and length little higher as compared to case 2 in Table 2. In contrast, combinations (ii) and (iii) yield practically identical results when compared with case 2 in Table 2. The clustering accuracy is found to be unaffected by the perturbation in hyper-parameters, with all three combinations resulting in similar values of ARI. The results are also found not to be sensitive to moderate perturbations of hyper-parameters $a_\sigma$ and $b_\sigma$.

5 Brain Connectome Dataset with the Creative Achievement Questionnaire (CAQ)

Our dataset of interest consists of brain connectome information on several subjects collected using a brain imaging technique called Diffusion Weighted Magnetic Resonance Imaging (dMRI). It is openly available in the Templeton 114 repository at https://neurodata.
io/mri. Note that dMRI is a magnetic resonance imaging technique that measures the restricted diffusion of water in brain tissues in order to produce neural tract images which are then pre-processed using the NDMG pre-processing pipeline (Kiar et al., 2016). In the context of dMRI, the human brain is divided according to the Desikan atlas (Desikan et al., 2006) that identifies 34 cortical regions of interest (ROIs) in each of the left and the right hemispheres of the human brain, implying 68 cortical ROIs in all. These 68 ROIs are contained in 6 lobes each in the left and the right hemispheres, namely the temporal, frontal, occipital, parietal, cingulate and insula lobes.

Using dMRI, a brain network for each subject is constructed as a symmetric matrix with row and column indices corresponding to different ROIs, and entries corresponding to the estimated number of ‘fibers’ connecting pairs of brain regions. Thus, for each subject, representing the brain network, is a symmetric matrix of dimension 68×68, with the \((j_1, j_2)\)th off-diagonal entry being the estimated number of fibers connecting the \(j_1\)th and the \(j_2\)th brain ROIs, and diagonal entries set to zero. For each subject, information on creativity as measured by the Creative Achievement Questionnaire (CAQ) is also available, which we treat as a feature of interest. Creative achievement can be perceived as an aggregate of creative products of an individual during his/her lifetime (Carson et al., 2005). CAQ, in particular, is a self-reported measure of creative achievement that assesses achievement across ten domains of creativity. To obtain the CAQ, each subject is given a questionnaire to complete, which is then used to form a comprehensive measure of creative productivity across ten domains, including visual arts, music, creative writing, dance, drama, architecture, humor, scientific discovery, invention and culinary arts. As a measure of creativity, CAQ has been recognized in the literature to be both reliable and valid (Jung et al., 2010). Along with brain network information and CAQ, age and sex are also available and are treated as auxiliary features for \(n = 73\) subjects in our dataset of interest. While there is earlier literature suggesting an effect of age on brain connectivity (Baum et al., 2017), all subjects in our dataset belong to the age group of 18-29 years with very little variation, which prompts us to ignore ROI specific age effects. We also find in the analysis in Section 5.1 that the age effects are practically insignificant in almost all the clusters, which further justifies our argument.

The main objective of the data analysis lies in supervised clustering of brain networks
of the 73 subjects. The Bayesian mixture model of network objects proposed in this article achieves clustering of subjects into different groups, each group having a different regression relationship of the brain connectome on CAQ, age and sex. The model offers inference on influential network nodes related to CAQ in different clusters, allowing for the scientific understanding of the relationship between creativity and the brain connectome with characterization of uncertainty in different groups/clusters of subjects. As a byproduct of our clustering exercise using the network mixture model, the normality assumption on the errors of the network response matrix is automatically relaxed. This is deemed appropriate for this dataset, since after fitting linear regression models independently on each cell of the network response matrix with CAQ, age and sex as predictors, we have observed visible non-normality in the standardized residuals (refer to the QQ plots of the standardized residuals for three representative cells in Figure 3).

5.1 Findings from CAQ Brain Connectome Data

This section reports analysis of the CAQ brain connectome dataset described in Section 5. We fit NRMM with $H = 20$, with the same set of hyper-parameters used in the simulation studies. NRMM, when applied to the CAQ dataset, identifies 7 clusters with 25, 13, 6, 6, 7, 8 and 8 subjects included in the clusters, respectively. Similar to simulation studies, the uncertainty in clustering is measured by the posterior probability of pairs of subjects lying in the same cluster, which is displayed through a heatmap in Figure 4(a). The figure indicates three distinct cluster assignments, with a somewhat higher degree of uncertainty among the
pairs lying outside these three clusters. The posterior distribution of the number of clusters (see Figure 4(b)) demonstrates some bimodality with modes at 6 and 7. Importantly, there is no posterior probability of having more than 9 clusters, suggesting that $H = 20$ is appropriate for this analysis.

In the absence of any ground truth, we compare the performances of NRMM and NRR with respect to the Posterior Predictive Loss Criterion statistic (Gelfand and Ghosh, 1998), which is calculated as $D = G + P$, such that a model corresponding to a lower value of $D$ is preferred. The $G$ values, representing a measure of model fit, turn out to be 98163.8 and 101738.7 for NRMM and NRR, respectively. The $P$ values, indicative of model complexity, are 101722 and 101489.2 for NRMM and NRR, respectively. Thus, the overall model fitting statistic $D$ shows a better performance of NRMM compared to NRR. HOLRR, being a frequentist method, is not included in this comparison. We also compute leave-one-out of sample mean squared prediction error (MSPE) for the three competitors and they turn out to be 0.64, 0.73, 0.71 for NRMM, NRR and HOLRR, respectively.

Similar to the simulation studies, we supply the model with the estimated cluster indicators and run it again to draw further inference on the influential nodes in the seven clusters. Notably, Cluster 3 includes individuals who are all male. Hence analysis of Cluster 3 does not include gender as a variable. To assess the model fit in each cluster, we calculate the mean
Table 5: MSPE, average coverage of 95% predictive intervals and average length of 95% predictive intervals for the seven clusters are provided.

Squared prediction error (MSPE), average coverage of 95% predictive intervals and average length of 95% predictive intervals averaged over all cells of the network response matrix and all subjects in a cluster. Table 5 depicts satisfactory point prediction along with an excellent characterization of predictive uncertainty. Referring to the high degree of non-normality in the error distributions discussed in Section 5, it is instructive to see if the mixture modeling framework justifies the normality assumption on the error distribution in each cluster. To check this, cell by cell Kolmogorov-Smirnov tests are conducted by comparing the discrepancy between the posterior mean of residuals and the normal distribution. Out of 2278 network matrix cells in each cluster, residuals in 51%, 62%, 18%, 96%, 91%, 89% and 97% cells in clusters 1 – 7, respectively, show statistically significant normality. Therefore, the normality assumption on the errors in each cluster is reasonable except for Cluster 3.

Figure 5 displays posterior densities of the age coefficients for all seven clusters. Except for Clusters 2 and 6, all other age coefficients turn out to be significant. Digging a bit deeper, we find that Clusters 2 and 6 show significantly lower variability in the ages of the subjects included, compared to the other clusters, which explains the age coefficient being statistically insignificant in these clusters. Also, except for Cluster 5, the posterior mean of the age coefficients are found to be negative in all other clusters, implying a negative association between creativity and age. In all six clusters where gender is added as a variable, it is found to be significantly related to creativity (see Figure 6).

To assess which nodes are related to creativity (as measured by CAQ) in each cluster, we run the analysis in each cluster 10 times and report the nodes which have posterior probability of being active greater than 0.5 for at least five of the replications. Figure 7 records the 10, 40, 30, 37, 41, 49 and 15 ROIs significantly related to CAQ in the 7 clusters of individuals. A considerable proportion of ROIs detected in each cluster are part of the frontal, cingulate and temporal lobes in both hemispheres. This finding concurs with results
Figure 5: Plots of age coefficient in each cluster. The 95% posterior credible intervals are shown through the space between the two dotted lines.
Figure 6: Plots of sex coefficient in each cluster. The 95% posterior credible intervals are shown through the space between the two dotted lines.
presented previously in the literature. In particular, the frontal lobe has been scientifically associated with divergent thinking, problem solving ability, spontaneity, memory, language, judgement, impulse control and social behavior (Stuss et al., 1985; Razuminkova, 2007; Miller and Milner, 1985; Kolb and Milner, 1981). Prior scientific studies also suggest that increased cortical volume of the superior frontal gyrus, and ventromedial prefrontal cortex, and decreased volume of the dorsal and rostral anterior cingulate cortex are associated with CAQ (Chen et al., 2014). Finkelstein et al., 1991 also report de novo artistic expression to be associated with the frontal and temporal regions. Our identification of the middle frontal gyrus and the inferior occipital gyrus being associated with CAQ is also supported by earlier scientific studies (e.g., Shi et al., 2017). Additionally, CAQ being related to the medial superior frontal gyrus and orbitofrontal insula have also been supported by previous studies (Chen et al., 2014).

6 Conclusion and Future Work

This article is motivated by the need to develop a flexible relationship between the brain network and creativity, as measured by CAQ, from subjects in a brain connectome dataset. Viewing the brain image for each subject as an undirected network, we propose a novel Bayesian mixture of regression models with a network response and scalar predictors. Our proposed framework clusters subjects into groups, with individuals in the same group sharing an identical relationship between the network response and scalar predictors. A spike-and-slab variable selection prior is assigned on the network node specific latent variables in each mixture component to deliver inference on influential network nodes significantly related to a specific predictor of interest. Empirical investigations with simulation studies validate our network response mixture modeling (NRMM) framework and yield superior inference over relevant competitors. The NRMM framework, when applied to a real brain connectome dataset, finds clusters of individuals sharing similar relationships between their brain networks and creativity, identifying brain ROIs significantly related to creativity in each cluster.

As part of future work, we envision investigating the performance of our model with a more flexible non-local prior structure on the node-specific latent variables. We also plan to
Figure 7: CAQ Data. Figure plots a 68 × 7 matrix with the rows and columns corresponding to the ROIs and clusters, respectively. A green cell in the \((k, h)\)th entry of the matrix implies that the \(k\)th ROI in the \(h\)th cluster is not significantly related to creativity. Prefix ‘lh-’ and ‘rh-’ in the ROI names on the \(y\)-axis denote their positions in the left and right hemispheres of the brain, respectively. The ROI names are color-coded according to the lobes they belong to. From bottom to top, the group of ROIs under the same color correspond to the temporal, cingulate, frontal, occipital, parietal and insula lobes.
extend our framework with each mixture component fitting a generalized linear model with a symmetric network/tensor response and scalar predictors.

Appendix

Posterior Full Conditionals

Let \( I_h = \{i : c_i = h\} \), \( n_h \) denote the cardinality of \( I_h \), \( y_i = (y_{i,j} : 1 \leq j_1 < j_2 \leq p) \) and \( y_h = (y_i : c_i = h)^T \), \( h = 1, ..., H \). Further assume, \( q = p(p-1)/2 \), \( \beta^*_{s,h} = \{B^*_{s,h,j} : 1 \leq j_1 < j_2 \leq p\} \) and \( J_k = \{j \in J : j_1 = k, \text{for some } s_1\} \). The full conditionals are in closed form and hence allow a Gibbs sampling procedure to sample posteriors. They are listed as following:

\[
\begin{align*}
\gamma^*_{0,h} &\sim N \left[ \frac{\sum_{i \in I_h} y_{i,s} - \sum_{s=1}^{m} \beta^*_{s,h} x_{is} - 1 \sum_{s=1}^{l} \gamma^*_{s,h} z_{is}}{\sigma^2} \right], h = 1, ..., H. \\
\gamma^*_{s,h} &\sim N \left[ \frac{\sum_{i \in I_h} y_{i,s} - \sum_{s=1}^{m} \beta^*_{s,h} x_{ih} - 1 \sum_{s=1}^{l} \gamma^*_{s,h} z_{ih}}{q \sum_{i \in I_h} z_{is}^2 / \sigma^2 + 1} \right], s = 1, ..., l; h = 1, ..., H. \\
\sigma^2 &\sim IG(a_\sigma + (nq)/2, b_\sigma + \sum_{h=1}^{H} \sum_{i \in I_h} y_{i,s} - \sum_{s=1}^{m} \beta^*_{s,h} x_{is} - 1 \sum_{s=1}^{l} \gamma^*_{s,h} z_{is} \right|^2 / 2) \\
M_{s,h} &\sim IW \left[ (S + \sum_{k : u_{s,h,k} \neq 0} u_{s,h,k} u_{s,h,k}^T), (\nu + \# \{k : u_{s,h,k} \neq 0\}) \right] \\
(\pi_{s,h,r,1}, \pi_{s,h,r,2}, \pi_{s,h,r,3}) &\sim Dirichlet(\nu^0 + \# \{\lambda_{s,h,r} = 0\}, 1 + \# \{\lambda_{s,h,r} = 1\}, 1 + \# \{\lambda_{s,h,r} = -1\}) \\
\lambda_{s,h,r} &\sim \text{Discrete distribution taking values } 0,1,-1 \text{ with probabilities } p_{s,h,r,1}, p_{s,h,r,2} \text{ and } p_{s,h,r,3}, \text{ respectively. Here } p_{s,h,r,1} = \frac{\pi_{s,h,r,1} J(A_{s,h})_{\lambda_{s,h,r}=0}}{\pi_{s,h,r,1} J(A_{s,h})_{\lambda_{s,h,r}=0} + \pi_{s,h,r,2} J(A_{s,h})_{\lambda_{s,h,r}=1} + \pi_{s,h,r,3} J(A_{s,h})_{\lambda_{s,h,r}=-1}} \text{ and } p_{s,h,r,2,3} = 1 - p_{s,h,r,1} - p_{s,h,r,2}. \text{ Here } J(A_{s,h}) = \prod_{i \in I_h} N(y_{i,s} | \gamma^*_{0,h} + \sum_{s=1}^{m} \beta^*_{s,h} x_{is} + 1 \sum_{s=1}^{l} \gamma^*_{s,h} z_{is}, \sigma^2 I). \text{ } J(A_{s,h})_{\lambda_{s,h,r}=0} \text{ and } J(A_{s,h})_{\lambda_{s,h,r}=1} \text{ denote } J(A_{s,h}) \text{ evaluated at } \lambda_{s,h,r} = 0, 1, -1, \text{ respectively. Here } A_{s,h} \text{ is the collection of } \{\lambda_{s,h,r} : r = 1, ..., R\}. \\
u_{s,h,k} &\sim \mathcal{N}(\mathbf{u}_{s,h,k} \mid \mathbf{u}_{s,h,k}, \Sigma_{s,h,k}), \text{ where } \mathbf{U}_{s,h,J_k} = [U_{1,s,h,J_k} \cdots U_{n_h,s,h,J_k}]^T, \text{ } U_{i,s,h,J_k} \text{ has rows } (x_{is} \lambda_{s,h,1} \prod_{j=1,j_1 \neq k}^{2} u_{s,h,j}^{(1)}, ..., x_{is} \lambda_{s,h,R} \prod_{j=1,j_1 \neq k,j_2 \neq k}^{2} u_{s,h,j}^{(R)}) \text{. Further assume } \bar{y}_{i,j} = y_{i,j}-
\[ \gamma_{0,h} - \sum_{h_1=1}^{t} \gamma_{h_1,h} \hat{z}_{ih_1} - \sum_{h_2=1,h_2 \neq s}^{m} B_{h_2,h,j}^* x_{ih_2} ; y_{i,j}^* \] is a vector of collections of \( y_{i,j}^* \) over \( j \in J_k \) and \( y_{i,j}^* \) is a vector consisting of \( y_{i,j}^* \) over \( i \in I_h \). Also,

\[
\Sigma_{u_{s,h,k}} = \left( U'_{s,h,J_k} U_{s,h,J_k} / \sigma^2 + M_{s,h}^{-1} \right)^{-1}, \quad m_{u_{s,h,k}} = \Sigma_{u_{s,h,k}} U_{s,h,J_k} y_{J_k}^*/\sigma^2
\]

\[
w_{u_{s,h,k}} = \frac{(1 - \zeta_{s,h})N(y_{J_k}^*|0, \sigma^2 I) + \pi N(y_{J_k}^*|0, \sigma^2 I + U_{s,h,J_k} M_{s,h} U_{s,h,J_k}^T)}{(1 - \zeta_{s,h})N(y_{J_k}^*|0, \sigma^2 I)}
\]

- \( \xi_{s,h,k} \sim Ber(1 - w_{u_{s,h,k}}) \)
- \( \zeta_{s,h} \sim \text{Beta}(\sum_{k=1}^{p} \xi_{s,h,k} + 1; \sum_{k=1}^{p} (1 - \xi_{s,h,k}) + 1) \)
- \( P(c_i = h | \cdot) = \frac{\omega_h N(y_i|\gamma_{0,h}^* + \sum_{z=1}^{l} \beta_{0,h,z}^* x_{i,z} + \sum_{z=1}^{l} \gamma_{0,h,z}^* \hat{z}_{i,z}, \sigma^2 I)}{\sum_{d=1}^{H} \omega_d N(y_i|\gamma_{0,d}^* + \sum_{z=1}^{l} \beta_{0,d,z}^* x_{i,z} + \sum_{z=1}^{l} \gamma_{0,d,z}^* \hat{z}_{i,z}, \sigma^2 I)} \) for \( h = 1, \ldots, H \).
- \( v_{l_1}^* \sim \text{Beta}(1 + \# \{ i : c_i = l_1 \}, \alpha + \sum_{s=l_1+1}^{H} \# \{ i : c_i = s \}) \), \( l_1 = 1, \ldots, H - 1 \), \( \omega_1 = v_{l_1}^*, \omega_2 = v_{l_2}^*(1 - v_{l_1}^*), \ldots, \omega_{H-1} = v_{l_{H-1}}^* \prod_{l_{l_1}=1}^{H-2} (1 - v_{l_1}^*), \omega_H = \prod_{l_{l_1}=1}^{H-1} (1 - v_{l_1}^*) \)
- Parameter \( \alpha \) is updated using a Metropolis-Hastings algorithm.
