ABSTRACT

Evaluation of Acid Fracturing Based on the "Acid Fracture
Number" Concept. (May 2006)

Abdulwahab Alghamdi, B.S., King Fahd University of

Petroleum and Minerals, Dhahran-Saudi Arabia

Chair of Advisory Committee: Dr. Peter Valko

Acid fracturing is one of the preferred methods to stimulate wells in carbonate reservoirs. It consists of injecting an acid solution at high enough pressure to break down the formation and to propagate a two-wing crack away from the wellbore. The acid reacts with the carbonate formation and this causes the etching of the fracture surfaces. After the treatment, the created etched surfaces do not close perfectly and that leaves behind a highly conductive path for the hydrocarbons to be produced. We distinguish the issue of treatment sizing (that is the determination of the volume of acid to be injected) and the issue of creating optimum fracture dimensions given the size of the treatment. This is reasonable because the final cost of a treatment is determined mainly by the volume of acid injected and our goal should be to achieve the best performance of the treated well. The well performance depends on the created fracture dimensions and fracture conductivity and might change with time due to various reasons.

This research evaluates two field cases from Saudi Aramco where acid fracturing treatment has been used to stimulate a carbonate formation. I investigated the following

issues: a) how effective was the treatment to restoring the initial productivity, b) how did the productivity of the well change with time; c) what are the possible reasons for the change in performance, d) what are our options to improve acid fracture design in the future?

Based on our research work both near-well liquid drop-out and fracture-conductivity deterioration can impact the production in different proportion. Moreover, the fracturing model tends to overestimate the fracture conductivity in some cases as shown in SA-2. Also, the “Acid fracture Number” concept proves to be an effective way to evaluate the acid fracturing treatment. Several recommendations were made based on this research work as described in the last part of my thesis.

DEDICATION

This work is dedicated

To my parents for encouraging me to achieve this goal;

To my beloved wife, I want to say I love you Balqees and finally we can celebrate this
achievement together;

To all my brothers and sisters, Thanks for all you did for me and wishing you all good
health.

ACKNOWLEDGEMENTS

I wish to express my sincere appreciation to the following members of my graduate advisory committee for their contribution and continuous support to accomplish this research.

Thank you to the chairman of my graduate advisory committee, Dr. Peter Valko, for his endless support and continuous assistance in helping me to bring this research to completion.

Thank you to Dr. Stephen A. Holditch and Dr. Wayne Ahr for serving as members of my advisory committee and for the knowledge I gained from them.

I appreciate Dr. Hisham Nasr-El-Din and Dr. Zillur Rahim for providing me with the field data from Saudi Aramco.

Thanks also to faculty and staff of the Harold Vance Department of Petroleum Engineering at Texas A&M University for providing the facilities and accommodations to conduct my research.

Finally, I would like to thank Saudi Aramco for giving me this opportunity to do my M.S. Degree in a pioneer university in the Petroleum Industry.

CHAPTER I

INTRODUCTION

Acid fracturing is one of the fundamental ways to stimulate a well completed in a carbonate reservoir. The two main processes incorporated with acid fracturing are the etched fracture conductivity and the acid penetration distance. In a heterogeneous formation, acid fracturing has proved to be a successful method to enhance hydrocarbon recovery. Moreover, in a tight-gas reservoir, acid fracturing become the most economical method to produce the gas reservoir¹. Much research has been done to study acid penetration in acid fracturing.

The acid fracturing treatment data sets which were evaluated in this study were obtained from Saudi Aramco Oil Company. These treatments were performed on wells located in the giant Ghawar field. In the next section, I will describe the reservoir geology and I will define some of the critical parameters which affect the fracture geometry.

1.1 Reservoir Geology

The Ghawar structure is located in the eastern region of Saudi Arabia. This gigantic field stretches over a 225 km x 25 km (140 miles x 15 miles) and produces gas from its Pre-Khuff and Khuff carbonate reservoirs (see **Fig. 1.1**).

This thesis follows the style of *SPE Journal*.

Fig. 1.1-Ghawar field structure (after Rahim).¹

The distribution of sour gas and condensate content in the gas varies from one location to another in the same field. A typical Khuff well produces from approximately 15 – 30 m (50 – 100 ft) of net pay. The Khuff reservoirs are predominantly calcite and dolomite, interbedded with anhydrite in concentrations up to 15 wt% in the tighter sections.² Within the same section, there is a variation in formation lithology.

1.2 Khuff Formation

The Khuff formation is a deep gas carbonate reservoir that consists of dolomite and limestone sections in the eastern region of Saudi Arabia. The Khuff formation is an ideal candidate for acid fracturing because of the heterogeneous nature of the formation, which tends to help create the needed fracture conductivity.³ However, the variation in the fracture degree (fracture geometry), loss circulation while drilling, and early water breakthrough are a few among the most common problems encountered in these reservoirs.^{4,5}

The Khuff and Pre-Khuff are deep gas condensate reservoirs in an active tectonic stress environment.¹ This formation belongs to the late Permian age and lies between 11,000 and 12,000 ft. The Khuff formation is subdivided into four main zones, denoted as A, B, C, and D. The two main producing intervals of this reservoir are Khuff B and Khuff C. Both reservoirs tested and proved to have a high quantity of condensate rich gas. The average pay thickness in each reservoir estimated to be 110 ft and 180 ft for both Khuff B and Khuff C respectively.⁶

The next section summarizes some of the critical parameters and their impact on fracture geometry.

1.2.1 In-Situ Stress

An important mechanical property in fracture treatment design is the in-situ stress. In-situ stress impacts mainly the vertical and lateral growth of the fracture, and shapes the overall fracture dimensions. Several methods¹ can be used to calculate the in-situ stress profile. These techniques include over-coring, analysis of focal mechanisms of induced seismicity, size of borehole breakouts, core relaxation and Keiser effect.^{7,8} In the given field cases that I am going to evaluate in this study, the in-situ stress estimated by the most dependable method of calculating in-situ stress which is analyzing field pressure data from Microfrac and Minifrac treatments where fluid is pumped at a rate to barely create a fracture. The pumps are then shut down to measure the initial pressure drop (ISIP) and pressure drop with time as shown in **Figure 1.2**. Nolte's analysis or history matching technique is then used to determine fracture closure. In the Khuff formation

the in-situ stress measured to be 10,000 to 11,000 psi. Also, the vertical stress gradient across the Khuff reservoir estimated to be 1.1 psi/ft across the Khuff reservoir.^{7,8}

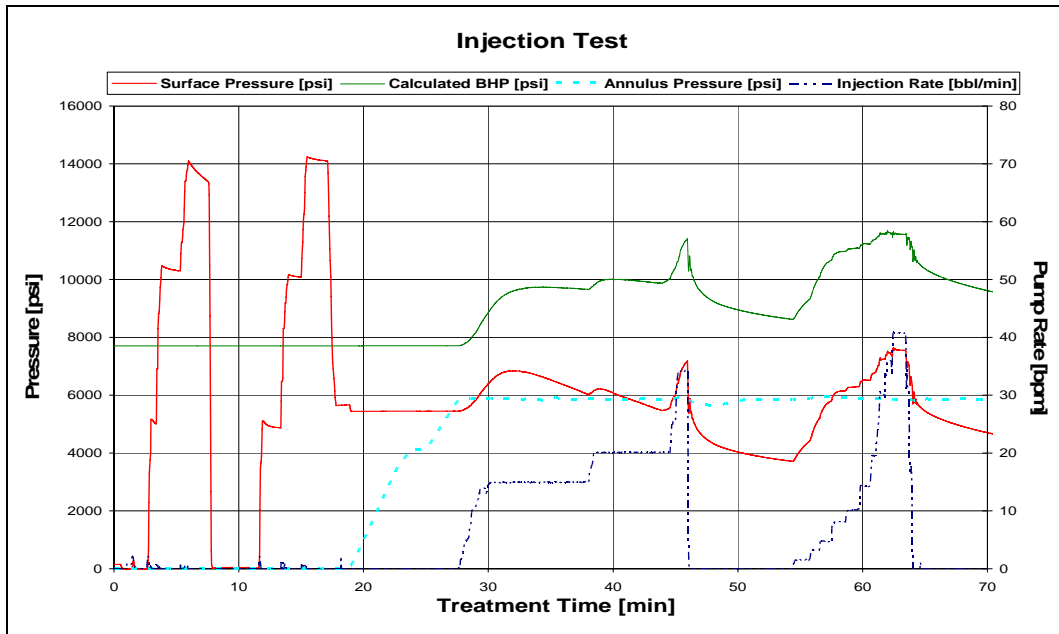

Fig.

1.2- Fracture pressure history match for SA-1.

1.2.2 Young's Modulus

Young's modulus, E , is the ratio of applied stress to the longitudinal strain. It can be interpreted as the rock "stiffness," or a parameter expressing the resistance of the rock to deform under a given tensional or compressional loading condition. Young's modulus is an important property that impacts the fracture geometry. Narrow fractures are created in formation with high modulus; whereas wide fractures are created in low modulus formations. The treatment must be carefully designed when high modulus values are encountered to avoid possible breakthrough into undesired intervals as the fracture have

a high tendency to create tall fracture.^{1,9} In the Khuff formation, the Young's modulus vary between 4E+6 and 9E+6 psi.

1.2.3 Poisson's Ratio

Poisson's ratio, ν , is the ratio of the lateral strain to the longitudinal strain. It represents the amount that the sides of a cube or core plug bulge out when the top is compressed. Poisson's ratio is always positive and less than 0.5.^{1,10} The Khuff formation has Poisson's ratio that ranges from 0.25 to 0.35.

1.2.4 Formation Permeability

The permeability reflects the ability of gas to flow within a formation. High permeability formations are more susceptible to formation damage during drilling, and may only require a matrix acid treatment for cleanup. In a low to moderate permeability reservoir, long fractures are required to effectively increase the productivity index. On the other hand, a short and conductive fracture might be best for a high permeability reservoir. As mentioned earlier the Khuff reservoirs are very heterogeneous formation and since it have average permeability of 0.5 – 4.0 md which suggested the second choice.⁷ The Khuff reservoirs have significant but variable porosity ranged from 0 to 35%.

1.2.5 Reservoir Pressure

Reservoir pressure affects the volume of hydrocarbon reserves, and the ability to flow back and cleanup the fracturing fluids after the treatment. The choice of fracturing fluid and also the success of a treatment can largely depend upon the reservoir pressure. The

average initial reservoir pressure in the khuff reservoir is 7,500 psi and the average bottomhole temperature is 275°F.

1.2.6 Fluid Leakoff Coefficient

The total fluid loss coefficient can be approximated with the following equation¹⁰

$$C_t = 0.047 \left(\frac{\Delta p \phi k}{\mu} \right)^{0.5} \dots\dots\dots 1.1$$

Where C_t is the total fluid loss coefficient and Δp is the pressure difference between the fluid in the fracture and in the formation. Better reservoir quality (porosity, permeability, pay thickness) increases fluid loss. The best method to compute C_t is through history matching minifracure treatments prior to pumping the actual treatment.

To control leakoff, industry has been using emulsions and acids gelled with polymers. Polymers are the most widely used because of its stability at high bottomhole temperature, especially in the presence of acid due to hydrolysis. Many carbonate formations contain micro-fractures ($\sim 5 \times 10^{-4}$ inch wide) and during acid fracturing, leak-off occurs through these micro-fractures as well as through the matrix.¹¹ Acid can increase the permeability of these fractures several thousand-fold and the leak-off control is always a challenge. The fluid-loss could be controlled to some extent by the use of alternating stages of pad fluids and acids.¹¹

The reaction of HCl with carbonate formations is fast, especially at high temperatures. This means that the acid will not be able to penetrate deeply down the fracture, which may affect the outcome of acid fracturing treatments. Polymers with and without cross-linkers can be used to reduce the rate of acid reaction with carbonate.

Nasr-El-Din and coworkers¹² reported lab results that indicated the polymer can be trapped in the wormholes and the crosslinker, especially iron, can precipitate in sour environments.¹²

The pad fluid that was used in these treatments were mainly viscoelastic surfactant fluids. The system is made by mixing a specific surfactant with HCl. Depending on the job requirement, the acid concentrations can vary from 5 to 28 wt% HCl. The VES-AC has low viscosity at surface conditions. The HCl present in the system reacts with the calcite as shown in **Equation 1.2**, or dolomite as shown in **Equation 1.3**. The by-products of the reaction are CaCl₂, MgCl₂, CO₂ and H₂O.

Calcite:

Dolomite:

The CaCl₂ that is produced as the acid spends will react with the surfactant in-situ to form a viscous gel. This increased in the viscosity will continue as the acid spends which will help to further minimize leak-off. In general, the viscoelastic surfactant works by itself without additives. However, Corrosion inhibitor is still needed to protect the tubing string. AbdulWahab *et al.*¹³ show that the corrosion inhibitor does not affect the viscosity of the VES system. The current application of the VES system include continuously injected of surfactant during pumping of the inert and acid fluids. This mixing procedure eliminates tank-bottom and the disposal of unused fluids. The use of

this mixing and pumping system will thus allow saving time and minimizing environmental impact.¹¹

1.2.7 Embedment Strength

Rock embedment strength is defined¹⁴ as the force required to push a steel ball bearing into the rock surface to a distance equal to the radius of the ball, divided by the projected area of the bearing. Higher embedment strength value indicates more competent rock. Embedment strength is measured in the laboratory and can vary between 30,000 psi to over 100,000 psi in the Khuff formation.¹⁵

Nasr-El-Din *et al.*¹⁵ made measurements on the Khuff formation using Brinellhardness (BH) methods before and after exposure to acid. Rock strength was reduced by 20 to 63 % after acidizing as shown in **Table 1.1**. The dolomite sample that was reduced 63 % was due to a higher degree of porosity and permeability from vugs. However, in my research work, I used the embedment stress as an average value of 100,000 psi considering the value needed for Nierode-Kruk correlation is the rock property before the acid reaction. Also I used 50,000 psi to see how the results would change.

TABLE 1.1-HARDNESS INFORMATION BEFORE AND AFTER ACIDIZING KHUFF CORE SAMPLES (AFTER NASR-EL-DIN).¹⁵		
Lithology	Rock Embedment Strength, psi	
	Before	After
Limestone	70,425	50,784
	51,072	31,494
	59,041	39,040
Dolomite	62,027	49,324
	129,988	47,647

1.3 Objectives

The objective of my thesis is to evaluate two field cases from Saudi Aramco where acid fracturing treatment has been designed and pumped. In this study we investigated the following issues: a) how effective was the treatment to restoring the initial productivity, b) how did the productivity of the well change with time; c) what are the possible reasons for the change in performance, and d) what are our options to improve acid fracture design in the future?

1.4 Organization of Thesis

My thesis includes seven chapters (I, II, II,and VII):

Chapter I presents the reservoir geology and the critical parameters which affect the fracture geometry. The other chapters organized as the following:

Chapter II presents the theory and the methodology I used in my calculation.

Chapter III summaries the field cases with the well description.

Chapter IV presents the fracture mechanism and the including the acid fracture program and the fluid system that was used.

Chapter V presents the evaluation part for the fracture geometry, bottomhole pressure, effective fracture conductivity and productivity index analysis

Chapter VI discuss the reasons of the production behavior and the possibility of proppant as an alternative.

Chapter VII presents summary, conclusions, and some recommendation for Saudi Aramco Oil company to assist their acid fracturing program.

Finally, I present the nomenclature, references, and three appendixes developed in this research.

CHAPTER II

THEORETICAL BACKGROUND

The creation of hydraulic conductivity created by acid etching was not fully understood for many years. One of the main concerns of scientists over the years has been to develop a method to calculate the expected fracture conductivity for an acid fracturing treatment. To design the optimal treatment, we have to be able to estimate the etched fracture length and the effective fracture conductivity as a function of the volume of the acid pumped down the fracture. In this study, I used the available correlation to estimate the fracture conductivity as part of my evaluation.¹⁴

A new application has also been developed in this study to apply the proppant number concept which was developed by Valko and Economides^{16,17,18} to acid fracture design and evaluation. The same concept can be applied by introducing the acid fracture number instead of the proppant fracture number.

In this chapter, I will discuss the theory behind the methodology I followed in my research starting by defining the dimensionless productivity index, and how it is related to the acid fracture number concept. Also, I will support the concept I applied to calculate both the flowing bottomhole pressure and the change in the fracture conductivity with time. Then, I will describe the gas well performance calculation. Finally, I will define the treatment evaluation methodology I used to investigate the change in the productivity index with time.

2.1 Dimensionless Productivity Index

One method to evaluate the performance of a well is to calculate the productivity index which is simply the production rate divided by the pressure drawdown

$$PI = \frac{q}{\bar{p} - p_{wf}} \dots\dots\dots 2.1$$

However, for a gas well equation (1) become,

$$PI = \frac{q\mu z}{p^2 - p_{wf}^2} \dots\dots\dots 2.2$$

The dimensionless productivity Index J_D is defined as

$$J_D = \frac{\alpha_1 B \mu}{kh} PI \dots\dots\dots 2.3$$

Similarly, for natural gas wells, J_D is

$$J_D = \frac{\alpha_2 \mu Z T}{kh} PI \dots\dots\dots 2.4$$

Later on we will see more details about the gas well performance and the use of J_D in that calculation.

The dimensionless productivity index, J_D depends on two dimensionless parameters: the dimensionless fracture conductivity, C_{fD} and the penetration ratio, I_x

C_{fD} is given by:

$$C_{fD} = \frac{(kw)_{af}}{kx_f} \dots\dots\dots 2.5$$

and the penetration ratio is

$$I_x = \frac{2x_f}{x_e} \dots\dots\dots 2.6$$

Valko and Economides^{17,18} represent the above two dimensionless groups by introducing new dimensionless variable called N_{prop} . Similarly, N_{af} can be used in the case of acid fracture.

Hence,

$$N_{af} = I_x^2 C_{fD} = \frac{4x_f (kw)_{af}}{kx_e^2} = \frac{4x_f (kw)_{af} h_p}{kx_e^2 h_p} \dots\dots\dots 2.7$$

Where $(kw)_{af}$ is described as the effective conductivity of the created acid fracture.

Therefore, at a given N_{af} and C_{fD} , the dimensionless productivity index can be determined using the chart developed by Valko and Economides. **Figures 2.1 and 2.2** can be used if both N_{Ac} and C_{fD} have been calculated.

Fig. 2.1-Fracture performance as a function of dimensionless fracture conductivity for low acid number. Reproduced from SPE paper 73758.¹⁸

Fig. 2.2-Fracture performance as a function of dimensionless fracture conductivity for moderate/high acid number. Reproduced from SPE paper 73758.¹⁸

2.2 Flowing Bottomohole Pressure Calculation

Since I do not have a measure value for the FBHP for the field data cases I have evaluated in this research, I have computed the values using surface pressure and nodal analysis. The traditional way of solving the problem can be done graphically as shown in **Figure 2.3**. The graph is a combination of inflow performance relationship (IPR) and vertical lift performance (VLP).

Fig. 2.3-Hypothetical case for combination of inflow performance relationship (IPR) and vertical lift performance (VLP).

For a single-phase flow of a compressible gas, **Equation 2.8**¹⁹ represents the VLP.

$$p_1^2 = e^{-s} p_2^2 - 2.685 \times 10^{-3} \frac{f_f (ZTq)^2}{\sin \theta D^5} (1 - e^{-s}) \dots\dots\dots 2.8$$

The unknown pressure is the upstream pressure P_1 .

Where s ,

$$s = \frac{-0.0375 \gamma_g \sin \theta L}{ZT} \dots\dots\dots 2.9$$

However, there are many simulation models that can do such calculations. In this study PERRFORM²⁷ model (see **Chapter V**) was used to calculate the FBHP.

2.3 Nierode and Kruk¹⁴ Correlation

The hydraulic conductivity created by acid etching is not totally understood. An empirical correlation for evaluating acid fracture conductivity was published by Nierode and Kurk over 20 years ago.¹⁴ To calculate the acid fracture number, the effective

fracture conductivity needs to be calculated. The fracture conductivity after the acid fracture treatment can be obtained directly from the fracturing model or can be estimated by using Nierode and Kruk correlation.

In the Nierode-Kruk correlation, the acid fracture conductivity is expressed as a function of ideal fracture width, which is determined from the amount of rock dissolved, the rock embedment strength and the closure stresses

We first compute the ideal width

$$w_i = \frac{XV}{(1-\phi) 2 h_f x_f} \dots\dots\dots 2.10$$

Then, we determine the effective fracture conductivity of the acid fracture from the ideal width, taking into account an additional formation strength parameter (rock embedment strength) and the net closure stress acting on the fracture faces.

$$k_f w = C_1 e^{-C_2 \sigma} \dots\dots\dots 2.11$$

$$C_1 = 1.47 \times 10^7 w_i^{2.47}$$

$$C_2 = (13.9 - 1.3 \ln S_{rock}) \times 10^{-3} \text{ if } S_{rock} < 20,000 \text{ psi}$$

$$C_2 = (3.8 - 0.28 \ln S_{rock}) \times 10^{-3} \text{ if } S_{rock} > 20,000 \text{ psi}$$

Figure 2.4 shows a Hypothetical diagram for the net closure stress which is a result of the minimum horizontal stress against the fracture opening face control be flowing botomhole pressure

Fig. 2.4-Hypothetical diagram indicates the physical meaning of the net closure stress which was used in Nierode-Kruk correlation.

The experimental studies show that the effect of rock heterogeneity is very important. However, the Nierode-Kruk correlation resulting from homogeneous rough walled and in case of rock heterogeneity the value can underestimate by this correlation due to the small sample size but the correlation still practical.

Recently, Gong *et al.*²⁰ made an important advance by developing a new correlation to predict the acid fracture conductivity where the roughness and the asperity of the rocks after acidizing were taken into account. Based on their experimental results, a new fracture deformation model was derived which considers both the surface roughness and the rock mechanical properties. Gong found that Acid fracture conductivity is affected by the aperture and the contact area of the fracture under closure stress. This in turn, depends on the surface asperities created by the acidizing process and the mechanical strength of these asperities. Also he showed that acid contact time, acid leakoff, rock mechanical properties and formation heterogeneity all affect the creation of hydraulic conductivity of an acid fracture.

Figure 2.5 shows a comparison between the Nierode-Kruk correlation and the new model done by Gong.²⁰ The results showed the new model agreed well with the measured conductivity, while the Nierode-Kruk correlation tended to over predict the conductivity at higher closure stress for different acidizing conditions. However, the new model needs measurement of the surface roughness distribution after acidizing. Part of my research is to calculate the theoretical fracture conductivity but since this information is not available in my case, I will use the Nierode-Kruk correlation to calculate the acid fracture conductivity.

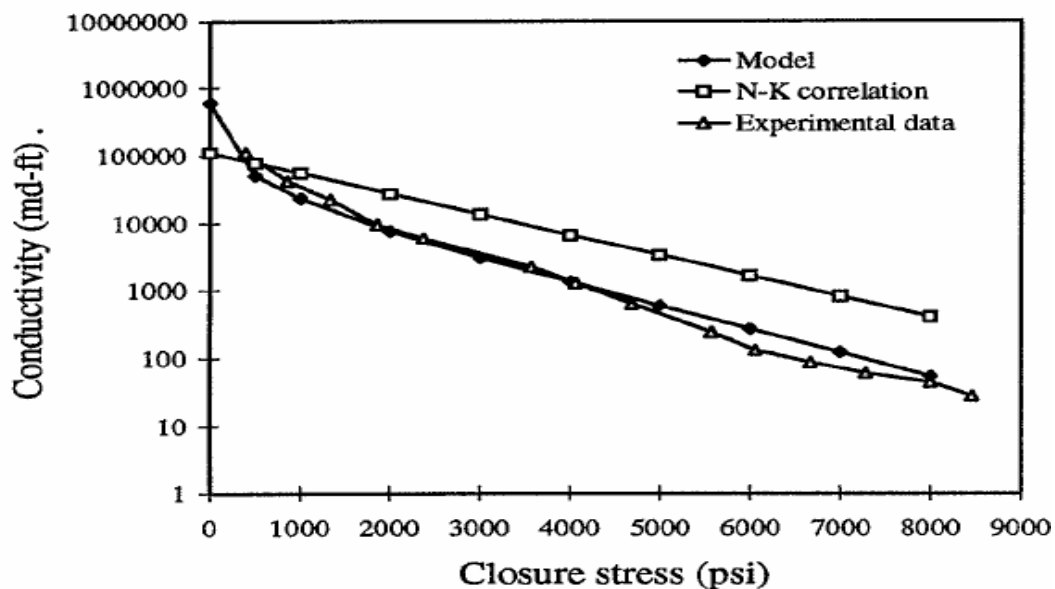

Fig. 2.5-Comparison between Gong model and Nierode-Kruk correlation. Reproduced from SPE paper 39431.²⁰

Nierode-Kruk¹⁴ correlation was based on the principle that the larger the amount of rock etched, the larger the conductivity of the fracture. However, Gong et al.²⁰ concluded that longer exposure times to HCl yielded more etching and higher conductivity. Navarrete²¹ has another point of view he said:

"This also leads to an inefficient use of the acid that tends to excessively spend at the wellbore, resulting in poor conductivity closer to the tip of the fracture. On the other hand, if the reaction rate is too slow, the amount of rock dissolved may be insufficient to prevent fracture closure."

"Although the most reactive system created 32 times more fracture volume, once closure stress was applied it did not result in higher conductivities. This suggests that it is more efficient to have the acid spend more uniformly along the fracture axis (emulsified acid) than mostly at the entrance. The added benefit of controlled acid spending is preservation of acid strength to generate longer fracture length. These results indicate that more fracture volume does not necessarily translate into higher conductivities."

2.4 Gas Well Performance¹⁹

For Pseudo-steady state and assuming Darcy flow, the gas flow rate, q (MSCF/d) can be estimated by using **Eqn.2.12** and solving for q:

$$p_{avg}^2 - p_{wf}^2 = \frac{1424q\mu zT}{kh} \frac{1}{J_D} \dots\dots\dots 2.12$$

The cumulative production from a gas reservoir, considering the expansion of the fluid is

$$G_p = G_i \left(1 - \frac{\frac{p_{avg}}{z}}{\frac{p_i}{z_i}} \right) \dots\dots\dots 2.13$$

Where z and z_i are the corresponding gas deviation factor at a given pressure and temperature

To compute G_i;
$$G_i = \frac{Ah\phi S_g}{B_{gi}} \dots\dots\dots 2.14$$

The gas formation factor B_{gi} , can be estimated by:

$$B_{gi} = 0.0283 \frac{ZT}{P} \dots\dots\dots 2.15$$

By using **Equations. 2.12 to 2.15**, one can develop a forecast for a gas well performance versus time until the average reservoir pressure declines to certain value depending on the available production data.

Another parameter to calculate is the time required to transition to pseudo-steady state from infinite acting behavior, which can be calculated by

$$t_{pss} = 1200 \frac{\phi \mu c_f r_e^2}{k} \dots\dots\dots 2.16$$

2.5 Treatment Evaluation Methodology Based on the Acid Fracture Number

According to the fracture number concept, the productivity index can be calculated if both dimensionless fracture conductivity and acid fracture number estimated. To answer the question regarding the change in the productivity of the well with time, I approached this subject from two perspectives:

2.5.1 Method (a)

The design model (FracCADE) predicts the fracture geometry. In addition, the Nierode-Kruk method was used to estimate the change in fracture conductivity with time. Using **Equations 2.5** and **2.7**, the dimensionless fracture conductivity and acid fracture number can be calculated, respectively. From the charts given in **Figures 2.1** and **2.2**, one can calculate the nominal productivity index (or nominal skin).

2.5.2 Method (b)

The actual productivity index of the well can be calculated from the monthly production data coupled with the calculated values of flowing bottomhole pressure which were estimated by using a nodal analysis computer program. Our analysis is based on comparing the two results. The results obtained from method (a) are the theoretical productivity index and the results obtained from method (b) are the actual productivity index. **Figure 2.6** describes the two methods applied to describe the change in the productivity of the well with time.

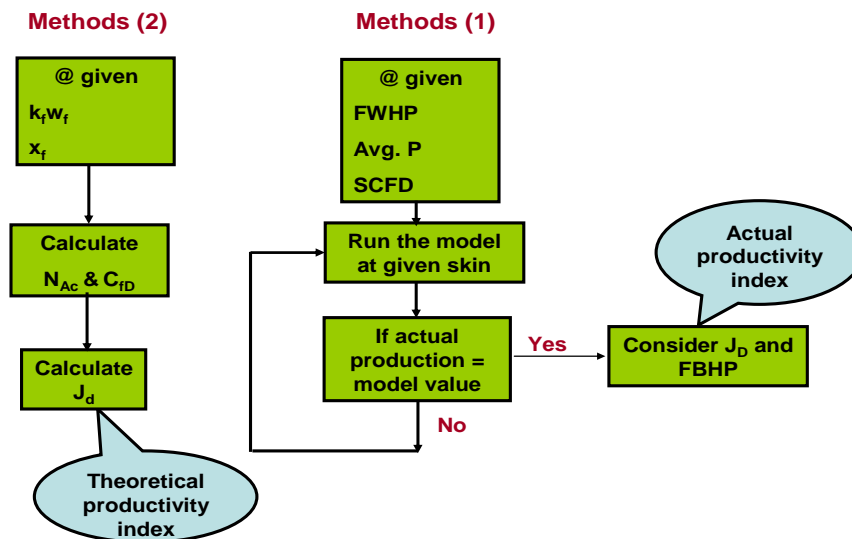

Fig. 2.6-Flow chart describes the two methods applied to describe the change in the productivity of the well with time.

CHAPTER III

FIELD CASES

Two field cases from Saudi Aramco where acid fracturing treatments have been pumped were evaluated in this study. In this chapter, I will describe the reservoir characteristics and the fracture geometry I consider important in my analysis. Also, the pumping schedule for the acid stages will be given for each case.

3.1 Well Description

Data from five acid fracture treatments have been received on wells SA-1, SA-2, SA-3, SA-4, and SA-5. The treated zones can be either Khuff-B or Khuff-C or a combination of both B and C as we will see in SA-3. However, we only had a production data for two of the wells.

3.1.1 Case Study-1: Well SA-1

SA-1 is gas well that was fractured with acid in the Khuff C zone. The well has two sets of perforations. The upper Khuff-C was perforated with 6 shots/foot between 11,400 and 11,525 ft. The lower Khuff-C was perforated from 11,525 to 11,575 ft with 1 shot/ft. The producing zones have permeabilities ranging from 1.22 to 4.0 md, with an arithmetic average permeability of 2.21 md, while the porosity varies from 7.5 to 20 %. The reservoir data are summarized in **Table 3.1**.

Layer	Start of Interval	End of Interval	Thickness of interval	Permeability (md)	Porosity, %	Kh, (md-ft)	Sg, %
1	11,402	11,425	23	1.22	8	28.06	70
2	11,440	11,452	12	1.50	12	18.00	85
3	11,458	11,500	42	1.44	10	60.48	85
4	11,501	11,525	24	1.18	7.5	28.32	40
5	11,525	11,575	50	4.0	20	200.0	88

The bottomhole temperature was estimated to be 270°F. This well has a net pay of 151 ft. The mechanical properties of the rock include a Poisson ratio of 0.29, and a Young's modulus of 6.1E+6 psi. The average in-situ stress is 10,400 psi at ~10,850 ft and average reservoir pressure is 7,500 psi. The well has a gas with specific gravity of 0.79 and a drainage area of 2250 acres. Additional average reservoir data and other well characterization data are given in **Table 3.2**.

Parameter	Value	Unit	Parameter	Value	Unit
Net pay	151.0	ft	Reservoir Temperature	270.00	oF
Permeability	2.22	md	Gas specific gravity	0.79	---
Growth thickness	173	ft	Reservoir pressure	7500	psi
Average porosity	11.5	---	Drainage area	2250	acre
Average gas saturation	73.6	---	In-Situ Stress	10,400	psi
Viscosity	0.035	cp	Bottomhole flow pressure	6,442	psi

Table 3.3 Summarizes the volumes of acid pumped into well SA-1. Details concerning the treatment are found in **Chapter IV**.

Stage Name	Slurry Rate (bbl/minute)	Pump Time (Minute)	Slurry Volume (bbl)	Acid Volume (gal)
Pad (polymer gel)/ Acid	48.5	9.3	451	16,879
Pad (polymer gel)/ Acid	58.4	7.4	432	16,172
Pad (VES)/ Acid	64.6	6.6	426	15,955
Pad (VES)/ Acid	67.4	8.9	599	22,447
Closed Fracture Acid	55.3	5	276	10,347

3.1.2 Case Study-2: Well SA-2

SA-2 is the second well we evaluated, and it was drilled to 11,377 ft depth and is completed in the Khuff-C zone. The permeability in this well ranges from 0.049 to 3.49 md. The porosity ranges from 6 to 18 %. This well was completed with 89 ft of perforations. The reservoir data are summarized in **Table 3.4**

Layer	Start of Interval	End of Interval	Thickness of interval	Permeability (md)	Porosity %	Kh, (md-ft)	Sg, %
1	11,377	11,387	10	3.49	17	34.9	85
2	11,389	11,398	9	1.28	10	11.52	78
3	11,400	11,430	30	0.84	8	25.2	76
4	11,460	11,470	10	3.88	18	38.8	80
5	11,502	11,532	30	0.49	6	14.7	75

This well has a bottomhole temperature of 250 °F. The average reservoir pressure is 7,505 psi. The mechanical properties of the rock include a Poisson ratio of 0.28 and a Young's modulus of 5.5 E+6 psi. The average in-situ stress is 10,830 psi. The well has a gas with specific gravity of 0.79 and a drainage area of 2250 acre. Additional average reservoir data and other well characterization are given in **Table 3.5**.

TABLE 3.5-SA-2 AVERAGE RESERVOIR DATA AND WELL CHARACTERIZATION					
Parameter	Value	Unit	Parameter	Value	Unit
Net pay	89	ft	Reservoir Temperature	250	°F
Permeability	1.4	md	Gas specific gravity	0.79	---
Growth thickness	155	ft	Reservoir pressure	7,505	psi
Average porosity	11.8	---	Drainage area	2250	acre
Average gas saturation	78.8	---	In-Situ Stress	10,830	psi
Viscosity	0.035	cp	Bottomhole flow pressure	5,917	psi

Table 3.6 Summarizes the volumes of acid pumped into well SA-2.

TABLE 3.6-PUMPING SCHEDULE FOR SA-2				
Stage Name	Slurry Rate (bbl/minute)	Pump Time (Minute)	Slurry Volume (bbl)	Acid Volume (gal)
Pad (polymer gel)/ Acid	38.9	9.8	381	11,207
Pad (polymer gel)/ Acid	45.8	8.3	380	11,176
Pad (VES)/ Acid	51.9	8.1	420	16,491
Pad (VES)/ Acid	51.7	8.3	429	16,833
Closed Fracture Acid	23.7	14.3	338	14,120

3.1.3 Case Study-3,4&5: Well SA-2,4&5

Appendix A includes the reservoir data, well characterization and the pumping schedule for the other study cases SA-3, 4, and 5. Well SA-3 was fractured in two acid fracturing treatments for Khuff-B and Khuff-C.

CHAPTER IV

PROCEDURE AND FLUIDS APPLIED FOR FRACTURING

A hydraulic fracture is created using hydraulic pressure to overcome the tensile strength of the rock and the minimum in-situ stress in the target formation. This force, as it overcomes the in-situ minimal horizontal stress, initiates a fracture perpendicular to the direction of the minimal stress. The effectiveness of any acid fracturing treatment depends on the effective fracture length and conductivity. The conductivity in an acid fracture treatment, in turn, will depend on the fluid loss, rock dissolution, and the damage associated with the treatment fluid.¹¹ Hydraulic fractures are usually considered near vertical and thus, its vertical plane aligns with the wellbore near the perforated portion of the well. However, since no wellbore is truly vertical, the fracture and the wellbore can easily deviated as the fracture height grows. The dimensions of vertical fractures depend on the geomechanical properties of the formation and excess pressure generated within the fracture. The main geomechanical property components that impact fracture propagation and geometry are the (1) minimum in-situ stress and (2) Young's modulus of the various rock layers that affect the fracture. Fracture vertical growth can be restricted if high stress difference is encountered between the interval fracture initiates and the intervals either above or below it. Both lateral and vertical fracture growths depend upon in-situ stress, net pressure, pumping fluid characteristics, and completion technique. Indeed, the location of perforation play an important role in determining fracture geometry and careful choice of perforations is needed for the success of a fracture treatment.^{22,23,24}

4.1 Acid Fracturing Computer Program

The fracture treatment fluids proposed for an acid fracture treatment take into account the following consideration; fluids selected to minimize formation damage, maximize effective fracture length, and enhance clean up efforts by decreasing clean up time. To this end, a polymer gel system coupled with a high temperature (HT) Breaker was selected for initial two pad volumes. A viscoelastic surfactant, micellar-gel was proposed for the third pad fluid, and subsequent gelled-acid stages for the main treatment. The high temperature VES system is designed to provide viscous fluid-loss control during injection; however, it will break down easily to a low-viscosity fluid with dilution by water, hydrocarbon, or mutual-solvent breaker solutions. VES fluids typically provide greater than 95% of fracture permeability retained, compared to 20-60% for polymer-based systems as a result of the formation damage caused by polymer. To ensure rapid breakdown/dilution of the viscous gels, an overflush of water containing 10 vol% mutual solvent was pumped. Additionally, two stages of emulsified preceded the gelled-acid stages, to achieve additional acid penetration and provide greater effective length/area. A final closed fracture acid stage at 20 wt% HCL was pumped at the end of the job to etch the critical matrix which helped in removing any near well bore damage. Burgos²⁵ reported that the effect the CFA stage on final productivity is not clear from the pressure data.

Table 4.1 summarizes the sequences of the fracture treatment schedule that was implemented to perform the acid fracturing treatment. Also **Table 4.2** includes more details about the pumped volume.

TABLE 4.1-THE SEQUENCES OF THE FLUIDS STAGES	
Stage Fluids	Acid Concentration
Pre-Pad ↓ polymer gel ↓ Emulsified Acid ↓ (VES)/ Acid ↓ Closed Fracture Acid ↓ Over-Flush	No Acid ↓ No Acid ↓ 28 wt% HCl ↓ 28 wt% HCl ↓ 28 wt% HCl ↓ No Acid

4.2 Fluid System

4.2.1 Initial Pad Volume

The purpose of initial pad volume is to

- Provide effective fracture extension by controlling leakoff.
- Cool down the formation to slow down the reaction rate.
- Create a wide and long fracture that will provide a conduit for the acid to flow into the reservoir.
- Saturate natural fractures and vugs to minimize acid leakoff.¹¹

The pad volume is calculated to create the length required to optimize stimulation for a particular formation, as well as vertical coverage of all pay zones of interest. If the pad volume is not too small, the created fracture may not be long enough to generate the optimal production. On the other hand, excess pad volume will not increase etched fracture area, as acid may already be spent before it reaches all created fracture. In some cases, increased pad volume may damage the formation. After performing several treatments with over forty thousand gallons of initial pad volume, the recommendation brought by Saudi Aramco engineers was to pump about 15,000 gallons of pad. This change in volume reduces the cost of acid fracturing while it does not compromise with the effectiveness of the treatments.²⁶ When acid is used without a pad fluid, the fracture will generally be short and narrow since the fluid loss for acid is high.

4.2.2 Acid Strength and Volume

The early development of the acid fracturing program consisted of pumping a viscous pad which is a combination of polymer and VES followed by 28% HCl. This type of design was an attempt to create fingering of the acid in the pad stages. Acid volumes of 28% HCl typically ranged from 1,500 - 2,000 gals/ft of treatment interval. A closed fracture acidizing stage with 28% HCl was pumped at the end of the treatment at a very low rate to increase the near wellbore etching and conductivity. Rahim et al.³ noticed that even though the treatments were pumped in excess of 50 bpm, the loss of net pressure resulted in creating shorter fracture lengths. Therefore, today's treatments are designed with 3-4 stages of alternating pad and acid with acid volumes of 800 - 1,200 gals/ft. This re-design has significantly improved the success of sustaining positive net pressure during the treatment. Along with the multiple stages of pad and gelled acid, emulsified acid was also introduced in an attempt to obtain deeper penetration of the stimulation fluids.³

CHAPTER V

EVALUATION

This chapter includes a complete analysis for the first two cases, SA-1 and SA-2. For the other three cases I compare the fracture geometry which was obtained by the design model with value obtained by the equations related to the acid fracture number concept. This comparison will be discussed in the next section

5.1 Fracture Geometry and Dimensionless Parameter

The design model predicts some of the fracture geometry parameters such as fracture half length, x_f , dimensionless fracture conductivity, C_{fD} , effective conductivity, kw_{af} and fracture width, w . In order to compare the design parameter with the value obtained by the dimensionless group equations given by **Eq's.2.5** and **2.7**. One can calculate these parameters and compare both results. In my research work I compared the design parameters as give by the fracCADE model (Approach 1) with the calculated parameters using **Eq's.2.5** and **2.7** (Approach 2). However in the two approaches the fracture half length assumed to be the design value.

5.1.1 Approach 1 (Fracture Geometry Parameters Obtained by fracCADE Model)

Approach 1 applies uses the fracture geometry that was predicted before the fracturing treatment using the design model (fracCADE) provided by the designing service company. In Approach 1, I used the fracture half length, average width, dimensionless fracture conductivity and effective conductivity from the model, FracCADE. However, I

calculated the acid fracture number using **Eq. 2.7**. After that, at a known value of (C_{fD}, N_{af}) , the dimensionless productivity index can be located in either **Figures 2.1** or **2.2**.

5.1.2 Approach 2 (Fracture Geometry Parameters Obtained by Dimensionless Groups Equations)

In Approach 2, I use the fracture half length only, and average width from the model design using fracCADE. After that, **Eqs. 2.5** and **2.7** can be used to calculate the dimensionless fracture conductivity and the effective conductivity respectively. Similar to the first approach, I calculated the acid fracture number using **Eq. 2.7**. Then, at a known value of (C_{fD}, N_{af}) , the dimensionless productivity index can be located in either **Figures 2.1** or **2.2**.

In Approach 2, I calculated the fracture width by using the ideal width formula, **Eq. 2.10**. The only fracture geometry parameter needed from the design program output is the fracture half length.

Also, the acid volume is needed to calculate the ideal width. That can be estimated from the design treatment provided by the service company. Knowing the slurry volume and the acid amount that has been added in each stage, one can calculate and the exact amount of the acid that has been pumped. **Table 5.1** summarizes the volumes of acid pumped into well SA-1. For that particular well, the total acid volume was 81,801 gallon. Using the dissolving power of 28 wt% HCl, the calculated fracture width is 0.19 inch. Column 3 and Column 4 in **Table 5.2** represents the data obtained with Approach 1 and 2 respectively.

TABLE 5.1-PUMPING SCHEDULE FOR SA-1				
Stage Name	Slurry Rate (bbl/minute)	Pump Time (Minute)	Slurry Volume (bbl)	Acid Volume (gal)
Pad (polymer gel)/ Acid	48.5	9.3	451	16,879
Pad (polymer gel)/ Acid	58.4	7.4	432	16,172
Pad (VES)/ Acid	64.6	6.6	426	15,955
Pad (VES)/ Acid	67.4	8.9	599	22,447
Closed Fracture Acid	55.3	5	276	10,347

SA-1: The design model provide an estimate of the fracture length of 378 ft, a value of dimensionless fracture conductivity of 34, fracture conductivity of 26,413 md-ft, and an average fracture width of 0.16 inch. Those values represent the Approach 1. Applying Approach 2, both the effective conductivity and the dimensionless fracture conductivity calculated to be 28,729 md.ft and 31, respectively. Also, the fracture width was calculated to be 0.19 inch. **Table 5.2** shows a comparison between the model values and the calculated values using the two approaches. The deviation percent indicate that there is a discrepancy between those values range from 5 to 15%. Using the "Acid Fracture Number" concept, the dimensionless productivity index can be estimated by knowing both acid fracture number, N_{Ac} and dimensionless fracture conductivity which was calculated to be 0.2 and 34.2 respectively. Based on the last two values, the dimensionless productivity index, J_D was estimated to be 0.37. This value reflects the performance of the well at the very early stage after putting the well on the production line following the acid fracturing treatment.

TABLE 5.2- SA-1 FRACTURE GEOMETRY AND DIMENSIONLESS PARAMETER				
Parameter	Symbol	Design Value	Calculated Value	Deviation %
Fracture Geometry				
Fracture half length, ft	x_f	378	378	---
Average width, in	w	0.16	0.19	15
Dimensionless fracture conductivity	C_D	34	31	10
Effective conductivity, md-ft	kw_{af}	26,413	28,279	6
Results from Acid fracture Number Concept				
Acid fracture number	N_{af}	0.19	0.20	5
Dimensionless productivity Index	J_D	0.37	0.38	2

Similar analyses were done to SA-2, as shown in **Table 5.3**. The dimensionless productivity index obtained by the first two approaches turned out to be the same, which reflects the overall productivity index. **Appendix A** includes the fracture geometry and the dimensionless parameter for the other cases.

TABLE 5.3- SA-2 FRACTURE GEOMETRY AND DIMENSIONLESS PARAMETER				
Parameter	Symbol	Design Value	Calculated Value	Deviation %
Fracture Geometry				
Fracture half length, ft	x_f	413	413	---
Average width, in	w	0.21	0.16	30
Dimensionless fracture conductivity	C_D	98.4	83.4	18
Effective conductivity, md-ft	kw_{af}	48,475	57,132	15
Results from Acid fracture Number Concept				
Acid fracture number	N_{af}	0.59	0.69	14
Dimensionless productivity index	J_D	0.38	0.39	2

The fracture width, which was calculated by the ideal width equation, has a value greater than the model value except, for SA-2, the deviation percent vary between 15 and 34%.

Figure 5.1 summarizes the fracture width with the deviation percent between the values obtained by Approach 1 and 2. Notice that Case 3 and 4 represent SA-3, K-B and SA-3, K-C respectively.

Fig. 5.1-Comparison between the calculated and the design fracture width for 6 acid fracture treatments. Where

- 1 = SA-1
- 2 = SA-2
- 3 = SA-3, K-B
- 4 = SA-3, K-C
- 5 = SA-4
- 6 = SA-5

5.2 Bottomhole Pressure Calculation

In this study, production data were available for only two of the wells, SA-1 and SA-2. The flowing bottomhole pressure (FBHP) was calculated using the inflow performance relationship (IPR) and the vertical lift performance (VLP). Because the procedure must

be done for more than 40 data point, it can be time consuming to do by hand. To computerize the process. I used the nodal analysis model PERFORM²⁷ to compute values for the FBHP model can be used

Well PERFORMANCE Analysis (PERFORM) is a graphical tool which can be used to analyze the performance of an oil or gas well. PERFORM can analyze multi-layer and /or multilateral reservoirs. Both production and injection wells can be modeled with both empirical and mechanistic pressure drop correlations. The model can be used friendly to calculate the inflow and outflow curves for a given well, using different nodes: bottomhole, wellhead and separator for onshore wells and bottomhole, top of tubing, riser outlet and flow-line outlet for offshore wells. In my study I used the FBHP (bottomhole flowing pressure) as a node.

The data required by the model to perform the calculation for each FBHP are listed in **Table 5.4** for SA-1.

TABLE 5.4- DATA INPUT TO CALCULATE THE FBHP USING PERFORM		
Input	Value	Unit
Condensate Gravity	46.2	°AIP
Specific Gas Gravity	0.79	---
Inorganic Content	CO₂ = 1.53 H₂S = 0.9 N₂ = 8.5	%
Reservoir Temperature	270	°F
Reservoir Permeability	2.22	md
Reservoir Thickness	151	ft
Wellbore Radius	3.5	inch
Reservoir Radius	5553	ft
Casing / Tubing Diameter	6.094' and 4.778'	inch
Reservoir Pressure	7436	psi
Reservoir Skin	- 6.92	---
Wellhead Pressure	4788	psig
Output		
Bottomhole Flowing Pressure	6410	psi

In **Table 5.3** the last three input are the only values to change to calculate the FBHP at the end of each month in a specific well. These values include flowing wellhead pressure (FWHP), average reservoir pressure, and productivity index represented by skin factor.

After entering the data in **Table 5.4** in the simulation model, an example of the output results which include the calculated FBHP is shown in **Figure 5.2**. This data point is the calculated FBHP in SA-1 @ (2nd Month of production, FWHP = 4,788 psig, average reservoir pressure = 7,436 psig and skin = -6.93).

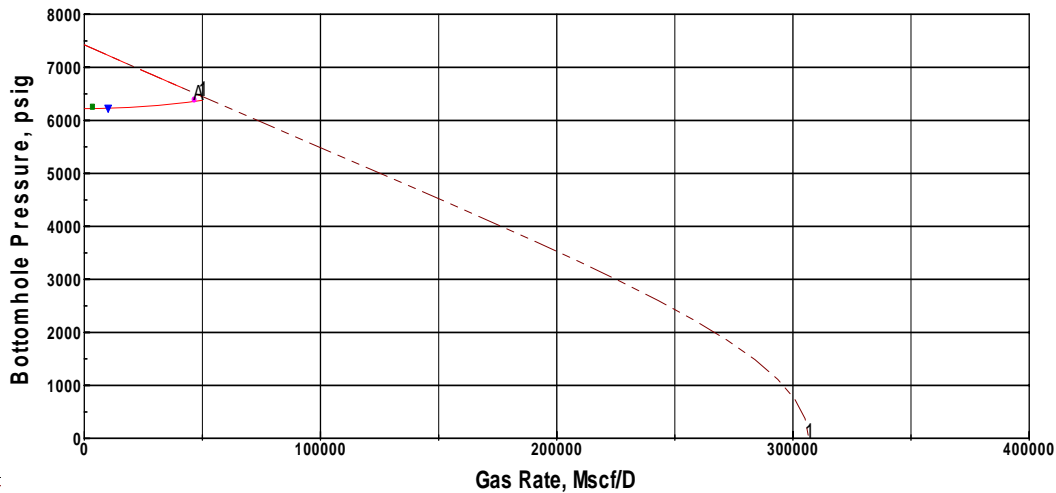

Fig. 5.2-Example of FBHP calculation using PERFORM, the plot represents a combination of inflow performance relationship (IPR) and vertical lift performance (VLP).

The same procedure can be repeated for each FWHP, and the FBHP can be calculated. **Table B.1** and **B.2** in **Appendix B** includes a set for the data needed by the model to calculate the FBHP for 25 month period of time with the output results for SA-1 and SA-2 respectively.

SA-1: **Figure 5.3** shows the change in the FBHP as the well being produced for long time. In this case the production data were available for more than two years. For the first 18 months, the FBHP decreased slightly from 6,442 to 5,839 psi. After that, there was a sharp drop in the FBHP along the following three months 19th, 20th, and 21st. Then the pressure level to about 4,500 psi. The cause of this decline will be discussed in the next chapter. The corresponding change in the reservoir pressure as shown in **Figure 5.3** described by gradual decrease from initial value of 7,500 to 6,806 psi with 10% reduction in the potential pressure of the reservoir. During the production interval the

choke valve has a back pressure between 1,270 and 1,622 psi with an average value of 1,478 psi.

Fig. 5.3-The change in the reservoir pressure, FBHP and FWHP with time for SA-1.

SA-2: In this case the behavior of the FBHP was fluctuating over a period of time as shown in **Figure 5.4**. At the beginning of the production time the FBHP estimated to be 5,752 psi. However, the FBHP decline in Sinusoidal shape. The lowest pressure occurs at about 5,000 psi. Many reasons can explain such instability as it will be discussed later. **Appendix B** includes a tabulated data for the different pressure values.

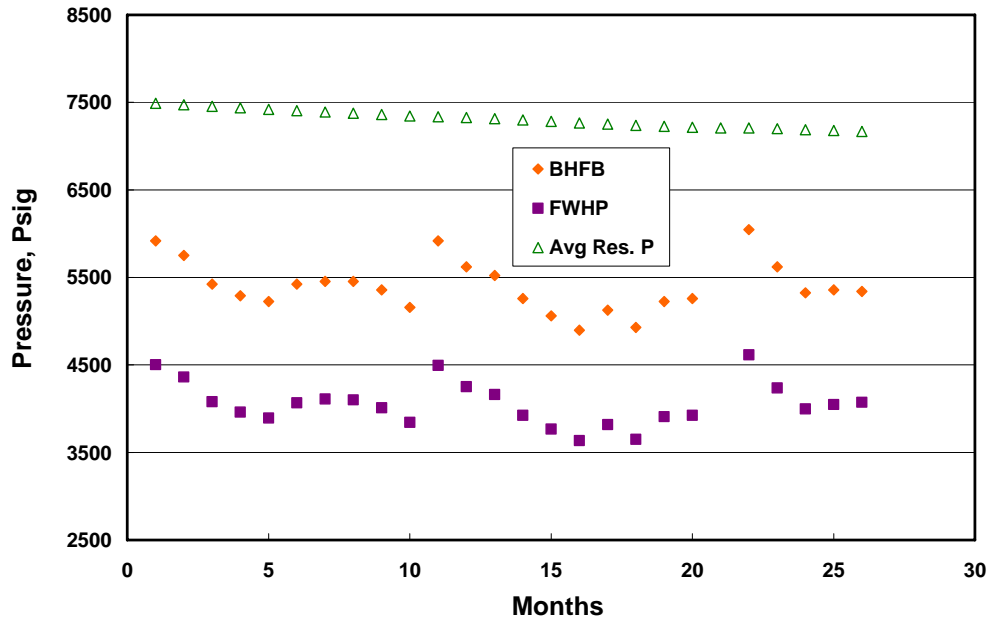

Fig. 5.4-The change in the reservoir pressure, FBHP and FWHP with time for SA-2.

5.3 Effective Fracture Conductivity

To calculate the fracture conductivity, I used Nierode-Kruk¹⁴ Correlation. Two important parameters affect the result significantly. First, rock embedment strength is very important. Second, the net closure stress acting on the fracture faces which is the difference between the in-situ stress and the FBHP. Based on literature review¹⁵ and personal communications, 100,000 psi chosen to be the embedment rock stress for such formation.

Figure 5.5 shows the calculated fracture conductivity against the change in the FBHP which is related directly to the closure pressure. Clearly, the higher FBHP the better conductivity as it will act against the minimum in-situ stress.

In case SA-1 the calculated fracture conductivity at the first month of production was 28,600 md-ft. This value was very close to the design value which was reported as

28,700 md-ft. According to Nerode-Kruk correlation the corresponding fracture conductivity to the decline in FBHP shows a sever reduction in the first one. The conductivity decreases from 28,606 md-ft to 9,259 md-ft. This number may not reflect the exact picture but still it shows how the fracture conductivity change as the closure stress increases.

However, in SA-2 the design value was 7 times grater than the calculated value which was reported as 57,132 md-ft. This difference suggested that, the design value was over estimated in some cases.

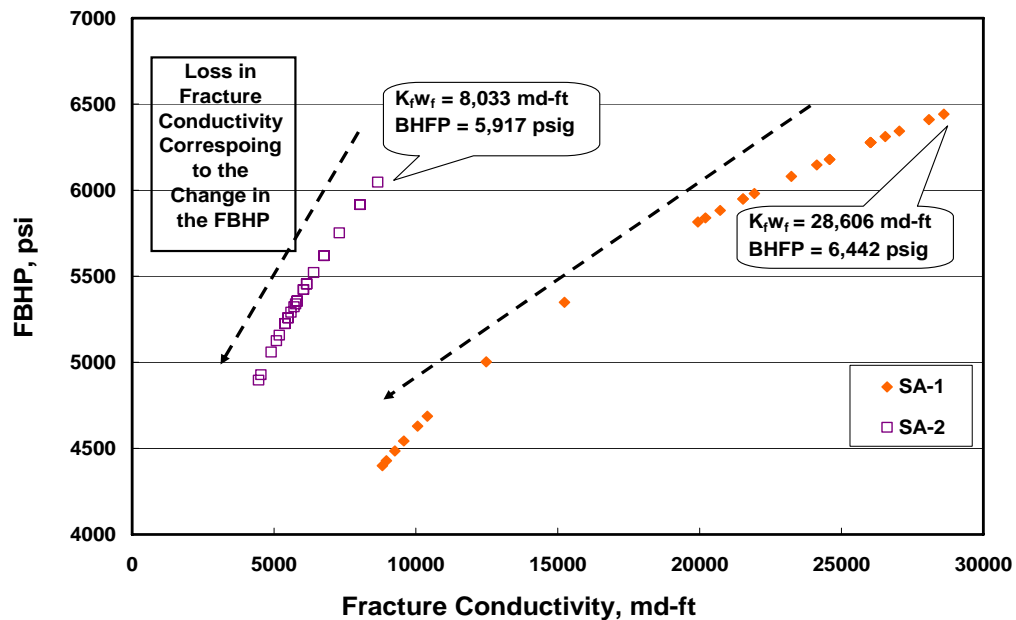

Fig. 5.5-The change in fracture conductivity as the FBHP decline with time.

5.4 Productivity Index Analysis

One of the main analysis to describe the performance of the well is to calculate the productivity index. This can be done by solving Eqs. 2.11 through 2.14. The

productivity index for SA-1 given in **Figure 5.6** indicates instability in the production at the first few months after the production. This was confirmed later as a result of transition to pseudo-steady state from infinite acting behavior which takes between 3 and 6 months. **Eq. 2.15** was used to calculate this time. After that the well continues producing until a sudden drop in the productivity index. In case of SA-1 the drop resulted in more than 40% reduction in the PI.

Fig.

5.6-The change in the productivity of the well with time for SA-1.

In SA-2 the productivity index decreases from 0.27 to 0.15 as shown in **Figure 5.7**. However, the trend shows the productivity index declines in three stages. At the beginning of each stage it looks like if the well is picking up some of the productivity but soon it declines again.

Fig. 5.7-The change in the productivity of the well with time for SA-2

To show the behavior of the productivity index if 50,000 psi chosen to be the rock embedment strength, similar analysis were done to calculate the productivity index using rock embedment strength of 50,000 psi as shown in Figure **Figs. 5.8** and **Figs. 5.9** for SA-1 and SA-2, respectively.

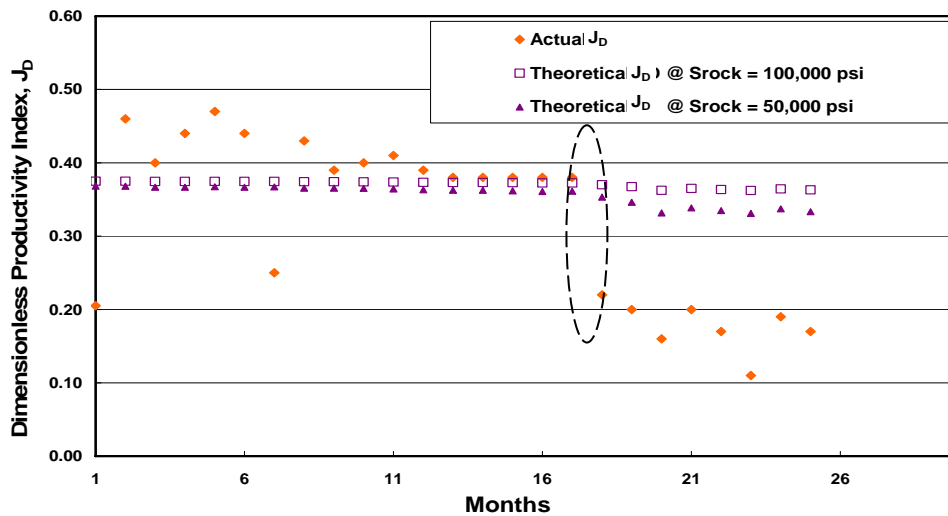

Fig. 5.8-The change in the productivity of the well with time for SA-1 @ $S_{rock} = 100,000$ and 50,000 psi.

Fig. 5.9-The change in the productivity of the well with time for SA-2 @ $S_{rock} = 100,000$ and 50,000 psi.

The estimated dimensionless fracture conductivity for SA-1 after the acid fracturing treatment decreases from 34 to 10 at constant J_D of 0.37 as **Figure 5.10** shows. This suggested that the well was over-fractured in terms of width. Similar thing happens in SA-2, the dimensionless fracture conductivity lowered from 14 to 10.

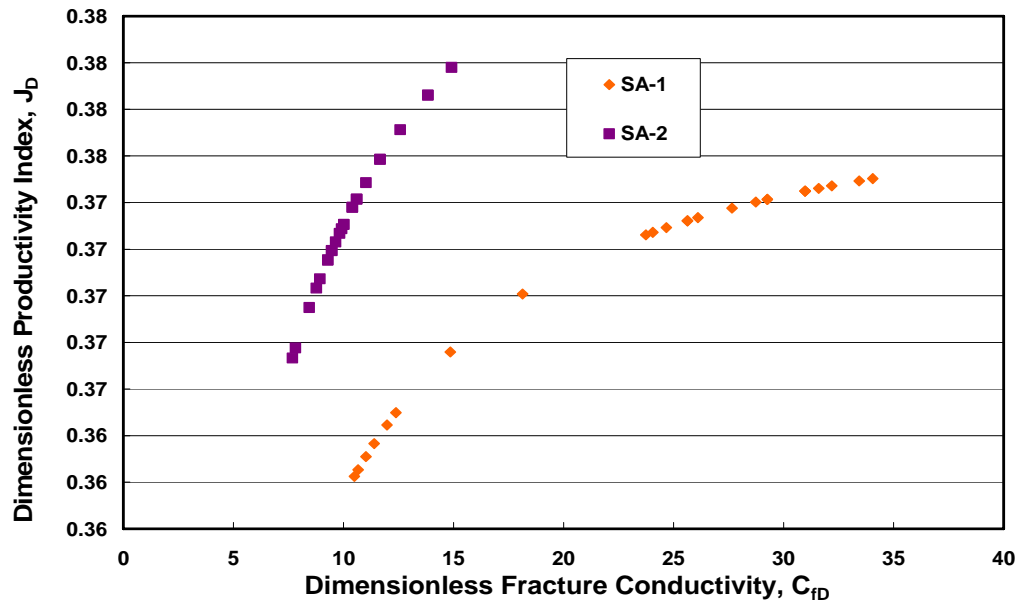

Fig. 5.10-The change in the J_D verses the dimensionless fracture conductivity.

Appendix B includes a list for the dimensionless group for SA-1 and SA-2.

CHAPTER VI

DISCUSSIONS

From **Chapter V**, it was clear that the PI changes over time. In this chapter, I will discuss several possible reasons which can cause such variation. These include:

- Liquid dropout as pressure reaches dew point.
- Net closure pressure effects on fracture conductivity.
- Non-Darcy effects on overall productivity.
- Pressure and in-situ stress effects on reservoir permeability.

I will focus on the first three items. However, the possible detritions of reservoir permeability is not included in this study.

6.1 Possible Reasons for the Change in the Productivity Index Behavior

6.1.1 Condensate Dropout

The fundamental mechanism in a gas condensate system can be describe as the rich gas approaches the wellbore, the pressure drops below the dew point causing liquid hydrocarbons to condense in the reservoir. Due to relative permeability effects, the effective permeability to gas is reduced, which decreases well deliverability. **Figure 6.1** shows how the condensate forms in the pore throat of the rock formation

Fig. 6.1-The accumulation of gas condensate in the pore-throat. (A) Pore-throat before condensate; (B) After condensate.

In order to plot the phase envelop, an accurate PVT data are needed for the gas composition. **Table 6.1** summarizes the component that represents the gas composition of SA-1. To validate the data, I did a flash point calculation and compare the PVTsim²⁸ results with the lab results as shown in **Table 6.2**.

Component	Well Stream Mole%
Nitrogen	7.6
Carbon Dioxide	0.93
Hydrogen Sulfide	0.00
Methane	72.61
Ethan	7.79
Propane	3.45
i - Butane	0.63
n - Butane	1.30
i - Pentane	0.44
n - Pentane	0.49
Hexanes	0.59
Heptanes	0.73
Octanes	0.74
Nonanes	0.61
Decanes Plus	2.09
Total	100.00

TABLE 6.2-FLASH POINT CALCULATION FOR SA-1				
Component	LAB Results		PVTsim ²⁸	
	Sep. Liquid Mole%	Sep. Gas Mole%	Sep. Liquid Mole%	Sep. Gas Mole%

Decanes Plus	25.5	0.00	26.68	0.04

Using the gas composition for SA-1, I was able to draw the phase envelop using the PVTsim²⁸. **Figure 6.2** shows the phase envelop for SA-1. From the graph it is clear to observe the dew point at 270°F as 5,650 psi. Therefore, any pressure in or around the wellbore fracture below 5,650 psi can result in condensate dropout and accumulation. Recall **Figure 5.3**, the decrease started after the 18th month at BHFP of 5,349 psi. This support the suggestion that the sudden decrease in the PI is dominated by the condensate blockage.

Fig. 6.2-Phase envelope diagram generated by PVTsim at a given gas composition.

Based on simulation studies Rahim *et al.*²⁹ reported that the near wellbore condensate saturation can quickly reach over 30% within 200-300 ft of radius.

Carlson *et al.*³⁰ investigate the effects of retrograde liquid condensation on a well productivity for a fracture well. In his paper, Carlson found that for a well containing a hydraulic fracture, the deliverability did not seem to be strongly affected by liquid drop out. These results appeared to contradict the other work done by other scientists such Fussell³¹ and the reason for that because in their work they had used an equivalent wellbore radius to account for the fracture effect. This approach apply the assumption of radial flow around the wellbore which imply significant reduction in the well deliverability is a result of condensate drop out. If this applied to the case I investigated, it support the suggestion that the reduction in the well I investigated was a result of sever reduction in the conductivity which makes the flow around the wellbore as radial flow and the condensate dropout is the real cause for such reduction.

In the second case, the productivity index did not show a sharp decline as SA-1. Since I do not have the gas composition it will be difficult to determine the dew point where the liquid comes out of the solution. However, since both well located in the same area and produce from similar zone, which means the phase envelop is going to be very similar. **Figure 6.2** shows that the dew point occurs at about 5,750 psi when reservoir temperature set at 250 °F. Going back to **Figure 5.4**, the well start producing at FBHP calculated to be 5,752 psi. Clearly this pressure is already at dew point which means the condensate blockage is acting. An important notice is that the slight decline in the production followed by stable or increase in some cases. This pattern was explained by El-Banbi³². He noted that the productivity inclines of the wells in a moderately rich gas condensate reservoir were observed to initially decrease rapidly, and then increase as the reservoir was depleted as explained by El-Banbi,

"During early production, a ring of condensate rapidly formed around each wellbore when the near-wellbore pressures decreased below the dew point pressure of the reservoir gas. The saturation of condensate in this ring was considerably higher than the maximum condensate predicted by the PVT laboratory work due to relative permeability effects. This high condensate saturation in the ring severely reduced the effective permeability to gas, thereby reducing gas productivity. After pressure throughout the reservoir decreased below the dew point condensate formed throughout the reservoir, thus the gas flowing into the ring became leaner causing the condensate saturation in the ring to decrease. This increased the effective permeability of the gas. This caused the gas productivity to increase as was observed in the field."

There are many ways to reduce the effect of gas condensate around wellbore area. One way is to inject lean gas (Cvetkovic et al., 1990).³³ Another way is to inject nitrogen (Sanger and Hagoort, 1998).³⁴ Many reasons limit the implementation of any of the previous methods either for economic reasons or for technical difficulties.

The producing rate of gas condensate reservoirs is affected greatly by the flowing bottomhole pressure. The value of the bottomhole pressure controls the amount and distribution of liquid condensate. Obviously, one way to prevent the formation of condensate is to maintain the FBHP to be above the dew point pressure. From practical point of view this is not possible since average reservoir pressure will drop as cumulative production reaches sensible values.

6.1.2 Changing Fracture Conductivity

There are two factors controlling the stability of the fracture conductivity. These two factors are the net closure pressure and the rock embedment strength. **Figure 6.3** shows how the fracture conductivity responds to the change in the embedment rock strength and the net closure pressure. The middle line belongs to SA-1 as the embedment strength change from 20,000 to 120,000 psi. Noticed that the value at rock embedment strength of 100,000 psi and closure stress of 4000 psi is the fracture conductivity of SA-1 which was estimate to be 28,600 md-ft after the acid fracturing treatment.

Fig. 6.3-The effect of embedment stress on the fracture conductivity at different net closure pressure.

As shown in **Figure 6.3**, Reducing the closure pressure in SA-1 at the early stage by 1,000 psi increase the fracture conductivity from 28,600 md-ft to 50,000 nd-ft.

6.1.3 Other Possible Reasons

Non-Darcy flow and changing permeability is another possibility for such decline. In the next section I will discuss the non-Darcy flow effect. However, the changing in the permeability is not covered in this study.

Non-Darcy flow is a result of any turbulence effect in the flow bath. In gas well, condensate can increase the turbulence as a result of introducing another phase to the system. The non-Darcy effect has more influence on the production decline as the rate increase. In Fracture well, this phenomena can be eliminated if a long fracture were

created to flow the gas from the reservoir to the wellbore. Since all the cases I tested have a fracture half length more than 300 ft, this length neglects the turbulence effects.

Rahim *et al.*²⁹ analyzed multi-rate test for similar cases. His observation was that all of the wells had build-ups following the last rate and none of the wells exhibited any turbulence effects during any of the flow or build-up periods of the test. As a result, turbulence can be neglected.

Gidley *et al.*³⁵ reported that a dimensionless fracture conductivity of 10 typically is assumed to provide a fracture so permeable in a way that formation permeability, not fracture permeability, controls the flow resistance. He mentioned that unless fracture conductivity is corrected for non-Darcy flow effects, this can cause a serious deficiency in fracture conductivity which will indicate less production than the expected one for the fracturing treatment. Gidley, Concluded that the dimensionless fracture conductivity can be corrected for non-Darcy flow by dividing it by the term $(1+N_{RE})$.

We found that non-Darcy flow can not explain the apparent change in productivity at later time because its effect should rather decrease with production decline.

6.2 Proppant Fracture as an Alternative

In both wells, the acid fracture number ranged from 0.1 to 0.2. In a medium permeability this can be the optimum scenario. However, since we are dealing with low permeability formation, massive hydraulic fracture is another option to consider resulting in J_D ranged between 1 and 1.5 as shown in **Figure 6.4**. To obtain this J_D , massive proppant fracturing treatment with larger acid fracture number is needed.

There are two reasons why proppant fracturing is recommended in this case. First, it will result in longer fracture. Second, proppant fracture is more reliable when maintaining conductivity becomes a concern.

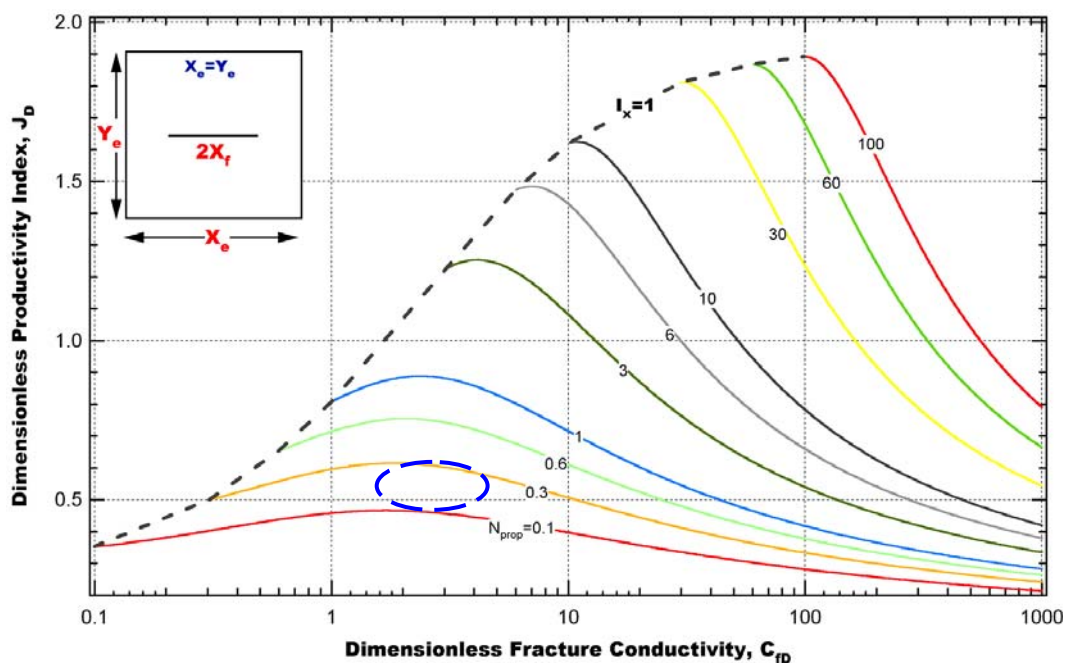

Fig. 6.4- Fracture performance as a function of dimensionless fracture conductivity for medium/high acid number. Reproduced from SPE paper 73758.¹⁸

Proppant fracturing can create longer fractures and has potential for application in such fields. Proppant fracturing of carbonate reservoirs is getting more attention in the industry.^{36,37,38} In proppant fracturing, a propping agent is used to keep the fracture open for the life of the well. Longer fracture half-lengths and sustainable conductivity are the leading drivers for this technology. However, for low-permeability reservoirs, longer fracture half length proved to be a main goal in such treatment. On the other hand, in high permeability reservoirs, fracture width is a key parameter to create better conductivity.

Wang *et al.*³⁹ showed that the production from gas condensate reservoirs should be a result of an optimization of distribution of the liquid condensate around the fracture. Two main fracture geometries should be design for an optimal value, the fracture half length and the fracture width. An important parameter to consider is the permeability.

The important of permeability comes from the fact that fracture face damage can be sever as a result of the penetration of polymer damage. In high-permeability cases this can significantly affect the production in. Whereas, the impact is less significant in low permeability. In the given study cases the permeability considered to be low and ranged from 0.5 to 4 md. Also, the fracture fluid was viscoelastic surfactant, the fluid prove to be a non-damage fluid and had a high efficiency to recover.⁸

CHAPTER VII

CONCLUSIONS AND RECOMMENDATIONS

7.1 Conclusions

On the basis of my research, we offer the following conclusions:

1. The fracturing model tend to overestimate the fracture conductivity in some cases as shown in SA-2
2. Production behavior response of all wells exhibits instability in the production for the first 3 to 6 months, which is the transition time to pseudo-steady state from infinite acting behavior and when the hydraulic fracture is closing.
3. The calculated fracturing width using the ideal width equation was 30% more than the design value.
4. Both near-well liquid drop-out and fracture-conductivity deterioration can impact the production in different proportion.
5. A possible reason for the sharp decrease in the productivity index is the liquid dropout.
6. Non-Darcy flow initially can not explain apparent change in productivity since its effect should decline with production decline.
7. The “Acid fracture Number” concept proves to be an effective way to evaluate the acid fracturing treatment.

7.2 Recommendations

Based on my research work, several recommendations were made as the following:

1. Better fracture conductivity leads to less draw down and maintains the flowing bottomhole pressure above the dew point.
2. Better design can be achieved with using the commercial fracturing model if integrated with “Acid Fracture Number” concept
3. It is necessary to know the condition of the well if already reach the dew point prior the acid fracturing.
4. It is recommended to measure the GOR to make better judgment about the condensate possibility.
5. The study cases have an acid fracture number ranged between 0.1 and 0.2. with this acid number the maximum productivity we can get is 0.6. Theoretically, since we have tide formation, a better hydraulic fracture should give productivity index range from 1.0 to 1.5 based on the acid fracturing number.
6. Proppant fracturing can help in maintaining the well performance for longer time if applied for optimal design.

NOMENCLATURE

A	Reservoir area, acre
B	Formation volume factor (resbbl/STB)
B_{gi}	Initial gas formation volume factor (resbbl/STB)
C_t	Total fluid loss coefficient
C_{fD}	Dimensionless fracture conductivity
D	Pipe diameter, inch
G_i	Initial gas in place, SCF
f_f	Friction factor
h	Net thickness, ft
h_p	Net Pay thickness, ft
I_x	Penetration ratio, x_f/x_e
k	Reservoir permeability (horizontal if not denoted), md
kw_{af}	Effective conductivity, md-ft
L	Length of vertical line, ft
N_{af}	Acid fracture number
\bar{p}	Average reservoir pressure, psi
p_{avg}	Average reservoir pressure, psi
p_{wf}	Flowing bottomhole pressure, psi
p_1	Upstream pressure, psi
p_2	Wellhead pressure, psi
q	Gas flow rate, MSCF/d

r_e	Equivalent drainage radius, ft, m
r_w	Wellbore radius, ft, m
S_{rock}	Rock embedment stress, psi
S_g	Gas saturation, %
T	Temperature, °R
T_{pss}	Pseudo-steady state, hr
V	Injected acid volume, bbl
w	Fracture width, in
w_i	Ideal width, in
x_e	Equivalent drainage length, ft
x_f	Fracture half-length, ft
X	Volumetric dissolving power
Z	Gas deviation factor
Z_i	initial gas deviation factor
μ	Viscosity, cp
α_l	Constant for appropriate units (141.2 for oilfield)
σ	Net closure stress, psi
\emptyset	Porosity
Δp	Net pressure in the fracture, psi
θ	Deviation from vertical, Degree
γ_g	Gas specific gravity
