Technical Report No. 41
Texas Water Resources Institute
Texas A&M University

June 1972
The primary objective of this research project is to develop techniques for the optimal operation of a linked system of multi-purpose reservoirs. Linkage of the system may be through normal river reaches, canals, or through pumping in pipelines. In this report a model is developed which utilizes stochastic inflows with the total system subject to certain constraints. This model will be utilized later in an operational study of an existing system.
ABSTRACT

In Chapter I of this report a model of a single multi-purpose reservoir with stochastic inflows is addressed. The objective of the model is the development of an optimal operating policy for given time sequence of minimum and maximum reservoir levels. The unregulated inflow into the reservoir is assumed to be stochastic with known distribution for each time period.

The significant difference between this model and those of previous investigators is that no linear decision rule is utilized. Instead, the approach is based on the distribution of the sum of the inflows over successive time periods. The resultant reservoir release variables are no longer stochastic values as they were in previous models.

The resultant constraint set forms a linear system of equations. Stochastic demands as well as inflows also are considered in the paper. Example problems are presented to illustrate the models.

In Chapter II, a single multi-purpose reservoir model with stochastic inflows is extended to a connected system of such reservoirs. The reservoirs are considered to be linked by a system of pumping canals and normal river reaches. The objective of the model is the optimal operation of the total system subject to certain restrictions on reservoir operations.

The linked system model is a natural extension of the single reservoir model proposed in Chapter I. The resulting constraints for the problem are linear and the decision variables are deterministic rather than random variables. Thus, linear, quadratic or even general convex objective functions can be handled readily.
ACKNOWLEDGMENTS

The work upon which this report is based was supported in part by funds provided by the United States Department of Interior, Office of Water Resources Research, as authorized under the Water Resources Act of 1964, P.L. 88-379.

We wish also to acknowledge the partial support provided by project number B-059-TEX, Dr. Wilbur L. Meier, Jr., Principal Investigator. Portions of the work were accomplished by Mr. James C. Helm, a graduate student in Industrial Engineering, while working on that project.

CHAPTER I

A STOCHASTIC MODEL FOR A SINGLE MULTI-PURPOSE RESERVOIR

Operations research methodology and systems analysis has in the last decade facilitated the water resource planner in the development of reservoir management techniques. The Planner must integrate the many functions of a reservoir in order to obtain decision policies.

In a recent paper ReVelle et al. (1969) proposed a linear decision rule for a single reservoir design and operation. The linear decision rule permitted the structure of a chance-constrained linear programming model for determining the reservoir capacity required to maintain a range of storage volumes and releases during specified time periods.

ReVelle's linear decision rule, as applied to a reservoir, has the simple form

\[ x = s - b, \]

where \( x \) is the release during a period of reservoir operation; \( s \) is the storage at the end of the previous period; and \( b \) is a decision parameter chosen to optimize some criterion function. The linear decision rule was applied in two contexts: (1) the stochastic contexts where the magnitudes of reservoir inputs are treated as random variables unknown in advance and (2) the deterministic contexts where the magnitude of each input in a sequence is specified in advance.

This article is an extension of the work of ReVelle for reservoir modeling. The emphasis will be mainly on stochastic systems since the deterministic case is merely a special case of the
stochastic model. The linear decision rule discussed by both ReVelle and Loucks (1970) is not utilized in this model. By not restricting the formulation to linear decision rules, several advantages arise. Paramount among these are the ability to include the release quantities $x_r$ in the objective function, the extension to a linked multiple reservoir system is readily obtained, and the inclusion of stochastic as opposed to deterministic demands adds no conceptional difficulties. This approach is applied initially to a single multi-purpose reservoir. The important case of systems of linked reservoirs will be taken up in a subsequent chapter.

Single Multi-purpose Reservoir

In this section a single multi-purpose reservoir with chance-constraints is modeled based on a formulated continuity or material balance equation. The formulation provides decisions that specify the release during different time periods of reservoir operation. The decisions for the entire time horizon are determined by solving a linear programming problem. The linear programming problem is the deterministic equivalent of the original stochastic system. The continuity equation consists of the reservoir inventory for the previous period, random inflow, deterministic demands, and scheduled releases.

Chance-constraints for each time period are established. Chance-constrained means that the specified constraints may not be satisfied all the time, but will be satisfied at least some pre-specified amount. The purpose of utilizing the chance-constrained formulation is the convenience in which the random variables can be handled in the constraints. The stochastic constraints selected involve maintaining (1) a specified maximum capacity minus a time requirement variable for upper storage space and (2) a time dependent minimum pool level.
The chance-constraints contain random inflow for each time period. The random inflows are assumed to be additive and essentially independent from one time period to the next. By making this assumption a density function for the sum of the independent random variables is obtained by convolution. The independence assumption is not necessary. It does, however, simplify the presentation of this approach and hence will be adhered to in further discussion. By using the convoluted random variables for each constraint, a deterministic set of equivalent linear constraints is generated.

Objective functions are then appended to this mathematical formulation for analysis of various decision policies. Both linear and quadratic objective function forms subsequently will be discussed. More general convex objective functions with linear constraints also can be handled readily (Rosen, 1961 and Goldfarb, 1969). However, the size of the general problem which can be solved routinely is much smaller than the more specialized linear and quadratic forms.

**Continuity Equation**

The continuity equation is based on the reservoir model shown in Figure 1.

![Figure 1: Single Multi-purpose Reservoir](image)
The total unregulated flow $\gamma_t$ enters the reservoir in time period $t$. The inflow is randomly distributed with a probability density function (p.d.f.) $f_r(\gamma_t)$. Therefore, the inflow in a particular period is known only with some probability. The inflow plus the storage volume $s_{t-1}$ at end of the previous time period is available for downstream release $x_t$, and extracted demands $d_t$.

The current ending storage volume or inventory level $s_t$ is then expressed as

\begin{equation}
 s_t = e_t s_{t-1} + \gamma_t - d_t - x_t,
\end{equation}

where $e_t$ is the fraction of water remaining contingent upon losses due to evaporation.

**Chance-Constraints with Stochastic Inflows**

The chance-constraint for the probability of not exceeding the specified maximum capacity of the reservoir is given by

\begin{equation}
 P\left\{ s_t < c_t - v_t \right\} \geq \alpha_t,
\end{equation}

where $c_t$ is the total capacity of the reservoir below the maximum water level, $v_t$ is the upper storage space which may be required in time period $t$ (this space might be reserved for flood control or surcharge storage), and $\alpha_t$ is a specified value between zero and one. The value of $\alpha_t$ is normally chosen to be reasonably close to one. The complementary probability $(1 - \alpha_t)$ represents the allowable risk that the random variable $\gamma_t$ will take on values such that

\[ s_t > c_t - v_t. \]

The probability at the end of time period $t$ that storage $s_t$ exceeds the minimum pool level $s_t$ is written as
\[ P \{ s_t \geq s_k \} \geq \alpha_c, \]

where \( \alpha_c \) is a preselected minimum allowable probability that must be maintained. The complementary probability \( 1 - \alpha_c \) represents the allowable risk that the random variable \( Y_t \) will take on values such that

\[ s_t < s_k. \]

The downstream release \( x_t \) must satisfy minimum \( x_k \) and maximum \( x_t \) reservoir release constraints

\[ x_k < x_t \leq x_t, \]

which might be established by water requirements for water control dilution, or recreational purposes.

**Convolution Formulation.** The chance-constraints can be converted to an equivalent set of linear constraint by convolution. The operation of obtaining the density function of the sum of two independent random variables is called convolution (Feller, 1966). The resulting p.d.f. is usually indicated as \( g_s = f_1 \ast f_2 \).

For the case of two continuous random variables \( x \) and \( y \) with a joint p.d.f. \( f(x,y) \), where \( -\infty < x < \infty \) and \( -\infty < y < \infty \), it is required to determine the p.d.f. of \( s = x + y \). To accomplish this it is necessary to consider the cumulative density function. (C.D.F.) of \( s \),

\[ G(s) = P \left\{ x + y \leq s \right\} \text{ or} \]

\[ G(s) = \int_{-\infty}^{s} \int_{-\infty}^{s} f(x,y) \, dx \, dy \]

in which \( -\infty < x < \infty, \) \( -\infty < y < \infty \),

and integrated over the range \( x + y \leq s \).
Changes in the limits of integration are then made to the C.D.F. and

$$G(s) = \int_{-\infty}^{+\infty} \left[ \int_{-\infty}^{s-x} f(x,y)dy \right] dx.$$  

Now, $G(s)$ is differentiated with respect to $s$ and the p.d.f. of $s$ is obtained

$$g(s) = \int_{-\infty}^{+\infty} f(x, s-x) dx.$$  

When $x$ and $y$ are independent, then

$$f(x,y) = f_1(x) f_2(y)$$

and the resulting p.d.f. of $s$ denoted by $g_s(s)$, is

$$g_s(s) = \int_{-\infty}^{+\infty} f_1(x) f_2(s-x) dx.$$  

For the case where it is required to obtain the convolution of three or more random variables the formulas are applied recursively until the density function of the total sum is obtained. As an example, let

$$s = x_1 + x_2 + \ldots + x_n,$$

where $x_1, x_2, \ldots, x_n$ are independent random variables. Then to obtain the p.d.f. of $s$, start first by obtaining the p.d.f. of $s_2 = x_1 + x_2$. Next with regard to $s_3 = s_2 + x_3$ and continue in this manner until $s_n = s_{n-1} + x_n$. 
The convolution operation also can be extended to the discrete case, that is,

\[ p_c(s) = \sum_{\text{all } x} p_1(x) p_2(s-x). \]

As an example of the discrete case, consider the density function of the random inflow \( \gamma_t \) into a reservoir over a certain time period \( t \) given by

<table>
<thead>
<tr>
<th>( \gamma_t )</th>
<th>0</th>
<th>1</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>( p(\gamma_t) )</td>
<td>.2</td>
<td>.3</td>
<td>.5</td>
</tr>
</tbody>
</table>

where \( \gamma_t \) is the number of units of inflow (usually expressed in day-second-feet or acre-feet) into the reservoir for the time period. Assuming that this distribution is the same for each time period and that each time period is statistically independent, find the distribution of random inflow for two time periods. By the application of the convolution formula, the discrete case yields,

\[
\begin{align*}
p(0) &= p_1(0) p_2(0) = .2 \times .2 = .04 \\
p(1) &= p_1(0) p_2(1) + p_1(1) p_2(0) \\
     &= .2 \times .3 + .3 \times .2 = .12 \\
p(2) &= p_1(0) p_2(2) + p_1(1) p_2(1) + p_1(2) p_2(0) \\
     &= .2 \times .5 + .3 \times .3 + .5 \times .2 = .29 \\
p(3) &= p_1(1) p_2(2) + p_1(2) p_2(1) \\
     &= .3 \times .5 + .5 \times .3 = .30 \\
p(4) &= p_1(2) p_2(2) = .5 \times .5 = .25
\end{align*}
\]
The distribution of the random inflow for the two time periods is

<table>
<thead>
<tr>
<th>$\gamma_1 + \gamma_2$</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
</tr>
</thead>
<tbody>
<tr>
<td>$p(\gamma_1 + \gamma_2)$</td>
<td>.04</td>
<td>.12</td>
<td>.29</td>
<td>.30</td>
<td>.25</td>
</tr>
</tbody>
</table>

**Deterministic Equivalent.** Chance-constraint (2) can now be converted to an equivalent linear constraint. For time period $t = 1$, substitute the continuity equation (1) into constraint (2) to yield

$$P \{ e_1 s_0 + \gamma_1 - d_1 - x_1 \leq c_1 - v_1 \} \geq \alpha_1.$$

The random variable $\gamma_1$ is taken to the right-hand side of the constraint and the inequality sign reversed to give

$$P \{ c_1 - v_1 - e_1 s_0 + d_1 + x_1 \geq \gamma_1 \} \geq \alpha_1.$$

Since $\gamma_1$ has a known p.d.f., the C.D.F. $F_{\gamma_1}$ evaluated at the argument

$$[ c_1 - v_1 - e_1 s_0 + d_1 + x_1 ]$$

must be greater than or equal to $\alpha_1$. Thus

$$F_{\gamma_1} [ c_1 - v_1 - e_1 s_0 + d_1 + x_1 ] \geq \alpha_1.$$

For specified $\alpha_1$, the chance-constraint becomes

$$c_1 - v_1 - e_1 s_0 + d_1 + x_1 \geq (R_1)^{\alpha_1}.$$
where \((R_1)^{C_1}\) is the value of \(\gamma_1\) from the cumulative distribution \(F_{\gamma_1}\) such that only 100 \((1-\alpha_1)\) per cent of the random values of \(\gamma_1\) are greater than the argument.

For \(t = 2\), constraint (2) is

\[
P \{ e_2 s_1 + \gamma_2 - d_2 - x_2 < c_2 - v_2 \} > \alpha_1.
\]

Substituting for \(s_1\) from the continuity equation (1),

\[
P \{ e_2 e_1 s_0 + e_2 \gamma_1 - e_2 d_1 - e_2 x_1 + \gamma_2 - d_2 - x_2 < c_2 - v_2 \} > \alpha_1.
\]

Grouping

\[
P \{ e_2 e_1 s_0 - (e_2 d_1 + d_2) - (e_2 x_1 + x_2) - c_2 + v_2 <
\]

\[-(e_2 \gamma_1 + \gamma_2)\}

and reversing the inequality sign the constraint becomes

\[
P \{ c_2 - v_2 - e_2 e_1 s_0 + (e_2 x_1 + x_2) + e_2 d_1 + d_2 \)

\[-(e_2 \gamma_1 + \gamma_2)\}

The C.D.F.

\[
F_{e_2 \gamma_1 + \gamma_2} \{
(c_2 - v_2 - e_2 e_1 s_0) + (e_2 x_1 + x_2)
\]

\[+(e_2 d_1 + d_2)\},
\]

which is obtained by convoluting the p.d.f.'s of \(e_2 \gamma_1\) and \(\gamma_2\), evaluated at the argument must be greater than or equal to \(\alpha_1\).
Again for specified $\alpha_1$, the chance-constraint becomes

$$(c_0 - v_0 - e_0 e_1 s_0) + (e_2 x_1 + x_2) + (e_2 d_1 + d_2) >$$

$$(e_0 R_1 \ast R_2) \alpha_1,$$

which is linear in $x_1$ and $x_2$. The expression $(e_0 R_1 \ast R_2) \alpha_1$ represents a value on the convoluted cumulative distribution of the random variables $\gamma_1$ and $\gamma_2$ evaluated at the point $\alpha_1$.

Then for the general nth time period, defining $e_n+1 = 1$,

(5) $P \left[ s_n \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \prod_{k=t+1}^{n} e_k \right] (\gamma_t - d_t - x_t) < c_n - v_n \right] \geq \alpha_1.$

The sum of the random variables is taken to the right-hand side of the constraint to give

$$P \left[ s_n \prod_{t=1}^{n} e_t - \sum_{t=1}^{n} \prod_{k=t+1}^{n} e_k \right] (d_t + x_t) - c_n + v_n$$

$$\leq - \sum_{t=1}^{n} \prod_{k=t+1}^{n} e_k \left\{ \gamma_t \right\} \geq \alpha_1.$$

Rearranging,

$$P \left[ c_n - v_n - s_n \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \prod_{k=t+1}^{n} e_k \right] (d_t + x_t) \right]$$

$$\geq \sum_{t=1}^{n} \prod_{k=t+1}^{n} e_k \left\{ \gamma_t \right\} \geq \alpha_1.$$
The C.D.F. for \( F_n = \sum_{t=1}^{n} \left( \prod_{k=t+1}^{n} e_k \right) \gamma_t \) evaluated at the argument is

\[
F_{x_n} \{ c_n - v_n - s_0 \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \left[ \prod_{k=t+1}^{n} e_k \right] (d_t + x_t) \} ,
\]

which must be greater than or equal \( \alpha_{1}^n \). By specifying \( \alpha_{1}^n \) the chance-constraint becomes

\[
( c_n - v_n - s_0 \prod_{t=1}^{n} e_t ) + \sum_{t=1}^{n} \left[ \prod_{k=t+1}^{n} e_k \right] (d_t + x_t) \geq
\]

\[
\prod_{t=1}^{n} \left\{ \prod_{k=t+1}^{n} e_k \right\} \gamma_t
\]

or

\[
(6) \ ( c_n - v_n - s_0 \prod_{t=1}^{n} e_t ) + \sum_{t=1}^{n} \left[ \prod_{k=t+1}^{n} e_k \right] (d_t + x_t) \]

\[
\geq ( R \otimes^n ) \alpha_{1}^n ,
\]

where \( ( R \otimes^n ) \alpha_{1}^n \) is the value at the \( \alpha_{1}^n \) point on the cumulative of the convoluted distribution.

Constraint (6) is the deterministic equivalent of (2), where the release quantities \( x_t \) are the decision variables. All other variables are state variables selected by the water resource planner.

Chance-constraint (3) is next converted to an equivalent linear constraint for two time periods followed by the general constraint for the \( n \)th time period.
Constraint (3) is

\[ P \left\{ s_t \geq s_t^* \right\} \geq \alpha_2, \]

and for \( t = 1 \)

\[ P \left\{ s_1 \geq s_1^* \right\} \geq \alpha_2. \]

Then, substitution of (1) into (3) yields

\[ P \left\{ e_1 s_0 + \gamma_1 - d_1 - x_1 \geq s_1^* \right\} \geq \alpha_2. \]

Taking the random variable to the right-hand side

\[ P \left\{ e_1 s_0 - d_1 - x_1 - s_1 \geq -\gamma_1 \right\} \geq \alpha_2 \]

and reversing the inequality yields

\[ P \left\{ (s_1 - e_1 s_0) + d_1 + x_1 \leq \gamma_1 \right\} \geq \alpha_2. \]

The deterministic equivalent for this equation, one minus the C.D.F., \( F_{\gamma_1} \), evaluated at the argument

\[ \left[ (s_1 - e_1 s_0) + d_1 + x_1 \right] \]

must be greater than or equal to \( \alpha_2 \). Thus,

\[ 1 - F_{\gamma_1} \left[ (s_1 - e_1 s_0) + d_1 + x_1 \right] \geq \alpha_2. \]
or

\[ F_{\gamma_1} \left[ ( s_1 - e_1 s_0 ) + d_1 + x_1 \right] \geq 1 - \alpha_2. \]

For specified \( \alpha_2 \) the chance-constraint becomes

\[ ( s_1 - e_1 s_0 ) + d_1 + x_1 \leq (R_1)^{1-\alpha_2}, \]

where \( (R_1)^{1-\alpha_2} \) is the value of \((1-\alpha_2)\) from the cumulative distribution \( F_{\gamma_1} \).

For \( t = 2 \), constraint (3) is

\[ P \left\{ s_2 \geq \frac{s_2}{\alpha_2} \right\} \geq \alpha_2. \]

Substitution of continuity equation (1) twice yields

\[ P \left\{ -e_2 x_1 + e_2 \gamma_1 - e_2 d_1 + e_2 e_1 s_0 + \gamma_2 - d_2 - x_2 \right\} \geq \frac{s_2}{\alpha_2} \geq \alpha_2. \]

Regrouping and reversing the inequality yields

\[ P \left\{ ( s_2 - e_2 e_1 s_0 ) + (e_2 d_1 + d_2 ) + ( e_2 x_1 + x_2 ) \right\} \leq ( e_2 \gamma_1 + \gamma_2 ) \geq \alpha_2. \]

As before, to obtain the deterministic equivalent for this equation, one minus the C.D.F. evaluated at the argument must be greater than or equal to \( \alpha_2 \).
\[ 1 - F_{e_0} \gamma_1 + \gamma_2 \left[ (e_2 - e_1 e_0) + (e_2 d_1 + d_2) + (e_2 x_1 + x_2) \right] \geq \alpha_2. \]

Letting \((e_2 R_1 \ast R_2)^{1-\alpha_2}\) represent the \((1-\alpha_2)\) value on the cumulative distribution \(F_{e_0} \gamma_1 + \gamma_2\), the deterministic constraint is

\[(e_2 - e_1 e_0) + (e_2 d_1 + d_2) + (e_2 x_1 + x_2) \leq (e_2 R_1 \ast R_2)^{1-\alpha_2}.\]

The generalized formulation of equation (3) follows that of equation (2) and the convolution of the sum of the random variables \(g_n\) is in general:

\[ g_n - s_0 \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \left( \prod_{k=t+1}^{k} e_k \right) (d_k + x_k) \]

\[ \leq \left\{ \prod_{t=1}^{n} (e_k R_t) \right\} \leq \alpha_2 \]

or

\[(7) (g_n - s_0 \prod_{t=1}^{n} e_t) + \sum_{t=1}^{n} \left( \prod_{k=t+1}^{k} e_k \right) (d_k + x_k) \leq (R_n \ast n) \leq \alpha_2.\]

Constraint (7) is the linear deterministic equivalent of (3) with the release \(x_t\) \((t = 1, 2, \ldots, n)\) being the decision variables necessary to insure that the storage \(s_n\) exceeds the minimum pool level \(g_n\) with a probability \(\alpha_2\).
Stochastic Inflows and Demands

The development for both stochastic inflows and stochastic demands is similar to that for stochastic inflows. The main difference is that the convolution of the inflows minus the demands must now be obtained.

Consider the general stochastic-constraint on reservoir capacity (5),

\[ P \left\{ s_o \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \left( \prod_{k=t+1}^{n} e_k \right) \left( \gamma_t - d_t - x_t \right) \leq c_n - v_n \right\} \geq \alpha_1. \]

The sum of the random variables \( \gamma_t \) and \( d_t \) is again taken to the right-hand side of the constraint and, upon rearranging,

\[ P \left\{ c_n - v_n - s_o \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \left( \prod_{k=t+1}^{n} e_k \right) x_t \geq \right. \]

\[ \left. \sum_{t=1}^{n} \left( \prod_{k=t+1}^{n} e_k \right) \left( \gamma_t - d_t \right) \right\} \geq \alpha_1. \]

The distribution of the random variable

\[ \xi_n = \sum_{t=1}^{n} \left( \prod_{k=t+1}^{n} e_k \right) \left( \gamma_t - d_t \right) \]

must now be obtained. This can be accomplished by convolution or by application of Fourier transforms (Farzen, 1960). Letting \( F_{\xi_n} \) represent the distribution function (C.D.F.) of \( \xi_n \), equation (8) becomes

\[ F_{\xi_n} \left\{ c_n - v_n - s_o \prod_{t=1}^{n} e_t + \sum_{t=1}^{n} \left( \prod_{k=t+1}^{n} e_k \right) x_t \right\} \geq \alpha_1. \]
Thus,

\[(9) \quad c_n - v_n - s_0 - \sum_{t=1}^{n} e_t + \sum_{t=1}^{n} (\prod_{k=t+1}^{n} e_k) x_t \geq R_{(\gamma^*_d)_n}^{\alpha_1},\]

where \(R_{(\gamma^*_d)_n}^{\alpha_1}\) represents the value of the random variable \(z_n\) for which \(100\alpha_1\) per cent of the area of the distribution is to the left of \(z_n\), or equivalently the \(\alpha_1\) point on the C.D.F. \(F_{z_n}\).

Constraint (9) is the deterministic equivalent of equation (2) when both the demands and inflows are stochastic. Similarly, equation (3) becomes,

\[(10) \quad s_n - s_0 - \sum_{t=1}^{n} e_t + \sum_{t=1}^{n} (\prod_{k=t+1}^{n} e_k) x_t \leq R_{(\gamma^*_d)_n}^{1-\alpha_2}.\]

The minimum and maximum constraints on releases remain as before. Hence, for stochastic inflows and demands, the constraints on the system are equations (9), (10), and (4).

Reservoir Models and Solutions

In this section three example problems are solved to illustrate the chance-constraint formulation. The first two example problems are solved by linear programming. One of the problems assumes stochastic inflow and the other example both stochastic inflow and demand. The third example problem append a quadratic objective function to the original model, which is then solved by quadratic programming.
Linear Objective Function with Stochastic Inflow

In the single multi-purpose reservoir example, it is assumed that the objective is to maximize the profit of releasing \( x_t \) units of water for two time periods. The releases are subject to the chance-constraints

\[
P \{ s_t < c_t - v_t \} \geq \alpha_1
\]

and

\[
P \{ s_t \geq s_t \} \geq \alpha_2
\]

from which the equivalent deterministic constraints (6) and (7) were derived.

For two time periods, constraints (6) and (7) are, respectively,

\[
\begin{align*}
\text{t=1} & : & - s_0 e_1 + d_1 + x_1 + c_1 - v_1 & > R_1^{\gamma_1} \\
\text{t=2} & : & - s_0 e_1 + d_1 + x_1 + s_2 & < R_2^{1-\alpha_2}
\end{align*}
\]

and

\[
\begin{align*}
\text{t=1} & : & - s_0 e_2 + e_2 x_1 + x_2 + e_2 d_1 + d_2 + c_2 - v_2 & > (e_2 R_1 \ast R_2)^{\gamma_1} \\
\text{t=2} & : & - s_0 e_2 + e_2 x_1 + x_2 + e_2 d_1 + d_2 + s_2 & < (e_2 R_1 \ast R_2)^{1-\alpha_2}
\end{align*}
\]
The maximum and minimum release constraints also must be satisfied:

\[ t=1 \]
\[ \begin{aligned}
& x_1 \geq x_i \\
& x_1 \leq x_i
\end{aligned} \]

and

\[ t=2 \]
\[ \begin{aligned}
& x_2 \geq x_i \\
& x_2 \leq x_i
\end{aligned} \]

By assuming the values in Table 1 for the state variables, the problem to be solved is

minimize \[ x_0 = x_1 + x_2 \]

subject to:

\[ -x_1 \leq 2 \]
\[ x_1 \leq 5 \]
\[ x_1 \leq 7 \]
\[ -x_1 \leq -1 \]
\[ -0.95 x_1 - x_2 \leq 11.1 \]
\[ 0.95 x_1 + x_2 \leq 5.9 \]
\[ x_2 \leq 8.0 \]
\[ -x_2 \leq -3.0 \]

Application of linear programming reveals the critical values of release \( x_1 \) and \( x_2 \) as 1 and 3 units, respectively, and a minimum cost \( x_0 \) of 4 units.

Linear Objective Function with Stochastic Inflow and Demand

In the previous example problem, only stochastic inflows were assumed. The distribution of inflows was known and the input to the program was listed in Table 1. In this example problem, the same system is assumed. Now, however, the demands and inflows are assumed to be normally distributed with means and variances listed in Table 2. The corresponding convoluted inflows and demands to be used in the problem formulation are also listed. The minimum reservoir level for time period two was adjusted to a unit value. This adjustment was necessary, since the previous problem with these inflows and demands is infeasible.

The solution to this problem is again obtained by the method of linear programming. The critical values of releases in periods one and two, \( x_1 \) and \( x_2 \), are 1.3474 and 3.0, respectively, with a maximum profit \( x_0 \) of 4.347 units.

Quadratic Objective Function

Consider a quadratic objective function for the same system as example 1. Let the objective be:

\[
\text{minimize } x_0 = x_1 + x_2 + 3 \left( x_1 - 3 \right)^2 + 5 \left( x_2 - 5 \right)^2 + 3 x_1 x_2 .
\]

The solution to this problem is readily obtained by quadratic programming techniques (Frank and Wolf, 1956, and Wolfe, 1959). The critical values of releases \( x_1 \) and \( x_2 \) are 1.0 and 4.6, respectively, with a minimum cost \( x_0 \) of 32.2 units.

</table>
Conclusions

In this paper an extension of the single multiple purpose stochastic constrained reservoir model was presented. The linear decision rules utilized by ReVelle et al. (1969) and Loucks (1970) are omitted in the model. The purpose of using linear decision rules is to disconnect the release in the nth period from the ending inventory level in period n-1. The advantage of a linear decision rule is that only the random inflow for the current period need be considered. However, the actual quantity to be released in the nth period is not known until the random inflows in periods 1 through n-1 are observed. Thus, for planning purposes where operation of the reservoir is important or when the release variables are represented in the objective function, this formulation is unsatisfactory since releases are actually random variables and not exactly determined by the reservoir planner.

The formulation proposed here requires that the distributions of the sums of the random inflows for all time periods be obtained. This is a relatively simple task for models with a large number of time periods. Since by the central limit theorem (Parzen, 1960), the distribution of the sums derived from the sampling of the parent distribution tends to become normal as the sample size increases.

By not using any form of decision rule, the constraints on upper and lower release quantities become deterministic and need not be represented by chance-constrained formulations. Also, quadratic or even general convex objective functions of the release quantities can be considered. The main advantage of this model is that it can be expanded readily to encompass systems of linked reservoirs with stochastic constraints.
CHAPTER II
STOCHASTIC MODEL FOR CONNECTED
MULTI-PURPOSE RESERVOIRS

In the previous chapter a chance-constrained model was proposed for a single multi-purpose reservoir. The model was based on a material balance equation and made extensive use of distributions of the sum of random variables. The natural extension of the single multi-purpose reservoir model is to link a system of such reservoirs.

Linked System of Multi-Purpose Reservoirs

For the development of a linked system of reservoirs, it is assumed that there are two general linkage types. These linkages consist of the normal channel flow for reservoir releases, and pipe lines or pumping canals. The model is completely general in the sense that any connecting system can be modeled. Thus, each reservoir could be connected to every other reservoir and could receive releases from any or all other reservoirs as dictated by the particular system under consideration.

For the purposes of this discussion, each reservoir in each time period is assumed to receive random unregulated inflow, regulated inflow from reservoir releases, and inflow from pumping. The reservoir level is depleted by means of scheduled releases, deterministic demands, evaporation and seepage losses, and pumping to other reservoirs. Stochastic demands can be handled by a simple extension to the model presented. The method of making this adjustment was indicated in Chapter I.

The system of multi-purpose reservoirs with chance-constraints is modeled based on material balance equations for reservoir inventory levels. The formulation provides decisions that specify the release
and pumping quantities during different time periods of system
operation. The release and pumping decisions for the entire planning
horizon are determined by solving a linear programming problem. The
linear problem is the deterministic equivalent of the original chance-
constrained system.

The chance-constraints for each reservoir and each time period
are identical to those developed for a single multi-purpose reservoir. The
random inflows for each reservoir are assumed to be independent
from one time period to the next. However, this assumption, while
simplifying, is not necessary to the model development.

**Continuity Equation**

The kth reservoir in the linked system is based on the model
shown in Figure 2 and the following notation:

- \( m \) - the number of reservoirs,
- \( \gamma_k^t \) - random unregulated inflow into reservoir \( k \) in time period \( t \),
- \( c_k^t \) - capacity of reservoir \( k \) in period \( t \),
- \( v_k^t \) - design maximum capacity in period \( t \),
- \( s_k^t \) - ending reservoir inventory level for period \( t \),
- \( s_k^* \) - minimum specified inventory level,
- \( e_k^t \) - fraction of inventory remaining after evaporation and
  seepage losses,
- \( x_k^t \) - scheduled downstream release from reservoir,
- \( p_{k,j}^t \) - scheduled pumping quantity from reservoir \( k \) to reservoir \( j \),
- \( p_{k,j}^* \) - maximum pumping capacity from reservoir \( k \) to reservoir \( j \),
\( x_t^{\text{z}} \) - maximum downstream release, \\
\( x_t^k \) - minimum downstream release, and \\
\( d_t^k \) - deterministic extracted demand.

![Diagram](https://example.com/diagram.png)

**Figure 2.** Linked Multi-purpose Reservoir

The total unregulated random inflow \( v_t^k \) enters the kth reservoir in time period t. The inflow is randomly distributed with a p.d.f. \( f_t(v_t^k) \). The regulated inflow \( x_t^j \) is the release from the jth reservoir into reservoir k. The regulated pumped inflow \( p_t^j \) is the water pumped from reservoir j into reservoir k. The pumping and release into reservoir k can be from several reservoirs, thus j can vary over all reservoir numbers.

The releases from the kth reservoir in time period t are (1) the deterministic extracted demands \( d_t^k \), (2) the decision variable for downstream release \( x_t^k \), and (3) the decision variable \( p_t^k \) for pumping water from reservoir k to reservoir j; again, reservoir k could pump to several different reservoirs. The releases plus the inflows and
previous storage volume constitute the current inventory level $s^k_t$. The continuity equation for reservoir $k$ in time period $t$ is

$$(11) \quad s^k_t = e^k_t s^k_{t-1} + v^k_t - d^k_t - x^k_t + \sum_{j=1 \atop j \neq k}^{m} (I^k_j d^j_t + O^k_j p^j_t - O^k_j p^k_t),$$

where

$$I^k_j = \begin{cases} 
1 \text{ if reservoir } j \text{ release flows into reservoir } k \\
0 \text{ otherwise, and}
\end{cases}$$

$$O^k_j = \begin{cases} 
1 \text{ if reservoir } k \text{ pumps to reservoir } j \\
0 \text{ otherwise.}
\end{cases}$$

**Chance-Constraints with Stochastic Inflows**

The chance-constraint for the probability of not exceeding the maximum capacity of the $k$th reservoir is

$$(12) \quad P \{ s^k_t < c^k_t - v^k_t \} \geq \alpha^k_t, \quad k = 1, 2, \ldots, m, \text{ and}$$

$$t = 1, 2, \ldots, T,$$

where $c^k_t$ is the design maximum capacity of the $k$th reservoir, $v^k_t$ is the upper storage space required in time period $t$ of the $k$th reservoir, and $\alpha^k_t$ are the specified constants between zero and one.

The probability $\omega^k_t$, at the end of time period $t$, for storage $s^k_t$ to exceed the minimum pool level is

$$(13) \quad P \{ s^k_t > s^k_t \} \geq \omega^k_t, \quad k = 1, 2, \ldots, m,$$
where $s_n^k$ is the minimum storage that must be maintained.

The downstream release $x_t^k$ must satisfy the minimum $x_{m_t}^k$ and the maximum $x_{M_t}^k$ reservoir releases constraints and maximum pumping capacity constraints, i.e.,

\[
\begin{align*}
  x_m^k & \leq x_t^k \leq x_{M_t}^k & \forall k, t, \text{ and} \\
  0 & \leq p_{j_t}^k \leq p_{j_t}^{-k} & \forall k, t, j.
\end{align*}
\]

The chance-constraints (12) and (13) are converted to their equivalent linear deterministic constraints in a similar manner as the chance-constraints of the single multi-purpose reservoir model. The general equivalent linear deterministic result for chance-constraint (12) with $t=n$ is

\[
\begin{align*}
(15) \quad c_n^k - v_n^k - s_n^k \prod_{t=1}^{n} e_t^k + \sum_{t=1}^{n} \left( \prod_{i=t+1}^{n} e_i^k \right) \cdot \left[ d_t^k + x_t^k - \sum_{j=1}^{\#k} \left( I_{j}^k x_j^k \right) + O_{k}^j p_{j_t}^k - O_{k}^k p_{j_t}^{-k} \right] & \geq R_{k, s_n^k} \beta^k,
\end{align*}
\]

where $R_{k, s_n^k} \beta^k$ are the values at the $\alpha^k$ points on the convoluted distributions. Chance-constraint (13) becomes

\[
\begin{align*}
(16) \quad s_n^k - s_n^k \prod_{t=1}^{n} e_t^k + \sum_{t=1}^{n} \left( \prod_{i=t+1}^{n} e_i^k \right) \cdot \left[ d_t^k + x_t^k - \sum_{j=1}^{\#k} \left( I_{j}^k x_j^k \right) + O_{k}^j p_{j_t}^k - O_{k}^k p_{j_t}^{-k} \right] & \geq R_{k, s_n^k} \left( 1 - \beta^k \right),
\end{align*}
\]
Figure 3: System of Connected Multi-purpose Reservoirs

The structure of the problem can now be put in the form

minimize \( Z = h \, y \)

subject to \( (A, I) y = b \),

\[ l \leq y \leq u \]

where

\[ u - l \leq 0 \]

and where \( y \) is the decision vector consisting of release, pumping, slack, and artificial variables.

1 \\
4.85 \\
.1
\end{bmatrix}
where \( R_{k \gamma}^{1-\alpha_k} \) are the values at the \( 1-\alpha_k \) points on the convoluted distributions. Equations (15) and (16) are linear in the decision variables \( x^k_t \) and \( p^k_t \). The releases and pumping units during different time periods of reservoir operation are, therefore, determined by solving a mathematical programming problem with linear constraints.

**Linear Objective Function**

The example presented is a system of multi-purpose reservoirs. Figure 3 is the model formulated for illustration. The linked reservoir system is composed of three reservoirs, two of which have pumping capabilities. Random inflows and predetermined demands are assumed for each reservoir. Table 3 describes the state variables assumed for each reservoir and time period. The objective is to minimize the operating cost of the system for two time periods.

The decision variables are to be determined for each time period. They are: the units of water released from reservoirs one, two, and three; and the number of units of water pumped into reservoir one from reservoirs two and three. The total number of variables to be determined is the product of the number of time periods with the sum of the number of reservoirs and pumping variables.

The decision variables must satisfy the equivalent deterministic constraints (15), (16), and the upper and lower limits on release (14). By taking advantage of the fact that the decision variables are bounded from above and below, the number of constraints can be reduced considerably for linear programming formulation of the problem. Using the bounded variable techniques discussed in Taha (1970), the resulting number of constraints is the product of twice the number of reservoirs multiplied by the number of time periods.
and an optimum cost of operating the system as -16.11 or a profit of 16.11 units.

Conclusions

The development of a mathematical model for a linked system of multi-purpose reservoirs with stochastic unregulated inflows is obtained as a straight forward generalization of the single reservoir model developed in Chapter I. The chance-constrained formulation for reservoir capacities and minimum inventory levels converts to a linear system of constraints. Linear, quadratic, or even general convex objective functions can be appended to this system and the solution obtained with facility.

The seemingly difficult, or at least time consuming, task of obtaining the distributions for the sums of the random inflows for models with many time periods is actually simple. As the number of time periods increase, the sum of random variables, independent of the basic distribution, are approximately normally distributed. This result is due to the well-known central limit theorem (Parzen, 1960).

If linear objective functions are assumed, which could be operational or of a capacity nature, very large problems can be solved. Since the cumulative inflows will be nearly normally distributed for these problems, their formulations and solutions are thus a matter of course. However, the problem of capacity expansion is generally not well modeled as a continuous linear problem. Capacity expansions are usually limited to certain periods and have nonlinear costs as a function of size.
CHAPTER III
PROGRAM DOCUMENTATION

The linear programming system which is used to solve the multiple reservoir chanced-constrained problems is based on the revised simplex method with bounded variables. The bounded variables procedure is a method by which constraints that are merely upper or lower bounds on individual variables are handled implicitly rather than explicitly in the program. Since the work involved in solving linear programs is mainly a function of the number of constraints, speed and accuracy can be improved significantly by utilizing the bounded variables procedure. This is particularly important for linked multiple reservoir models since at least one-half of the constraints are bounding constraints. A detailed discussion of the revised simplex procedure with bounded variables is given by Taha (1970, Chapter 8).

Although a large number of excellent codes are available, the authors developed the code which is used in the model. The program is FORTRAN based which offers the greatest flexibility for interfacing with the remaining subroutines and for conversion to other computers. The program was developed to run under the WATFOR, WATFIV or OS 360 FORTRAN systems on the IBM 360/65.

Program Structure

The basic structure of the computer program consists of a master program which reads the input data, develops the linear programming formulation, submits the problem to the linear programming subroutine LPSIM, and interprets the results for printout. The general problem solved by the linear program (l.p) subroutine is
maximize \quad c^T x

subject to \quad (A_1, I) x = b - a

\quad x^l < x < x^u,

where \( x \) is the decision vector and consists of release, pumping, slack and artificial variables. The variables are stored into \( x \) in the following manner (the notation is that given in the previous chapter):

all releases all pumping variables
\[
\begin{align*}
\text{time } 1 & : x^1_1, x^2_1, \ldots, x^8_1, p^1_{11}, p^2_{11}, \ldots, p^1_{21}, \ldots; \\
\text{time } 2 & : x^1_2, x^2_2, \ldots, x^8_2, p^2_{12}, \ldots, p^1_{22}, \ldots; \\
\text{time } T & : x^1_T, x^2_T, \ldots, x^8_T, p^T_{11}, \ldots
\end{align*}
\]

In narrative form the sequence of variables is (1) each release variable \( x^k_1 \) for each reservoir for time period one, followed by all first period pumping variables; (2) the pumping variables are ordered by all pumping into reservoir one, then reservoir two, etc.; (3) this sequence is repeated for each of the \( T \) time periods; and (4) the slack and artificial variables occur next, one each for every constraint.

Program Input Formats

The notation which is used in FORTRAN to designate whether a variable is an integer or a floating point variable is \( I \) or \( F \),
respectively. For I type variables, the data must be read in right adjusted in the field. For floating point variables, F designation, the decimal point must be included and the data inserted anywhere within the specified field. A field type of A is used for title information and can be any alpha or numeric character.

<td></td>
<td>2</td>
<td>I5</td>
<td>NR - number of reservoirs.</td>
</tr>
</tbody>
</table>

The remaining cards are read in sets. One set for each reservoir. All of the pertinent data for each reservoir is included within the set. Each reservoir in the system must be given a designation number; these numbers must be sequential starting with one. A title card also is included to identify the reservoir.

</tr>
</tbody>
</table>

(Repeat reservoir numbers until all reservoirs that are pumped to from this reservoir have been included. The maximum number on each card is 9 reservoirs on the first card. This is followed successively by 10 reservoirs per card. The limit of 9 on the first card is because NP takes up one field on this card.)

(The following set cards 4 and 5 are repeated for each reservoir pumped to from this reservoir or NP times. However, if no pumping is allowed from the reservoir omit set cards 4 and 5.)

<p>| 4        | 1     | F10  | pumping canal maximum capacity for first time period, |
